M/R: I received the report "Specifications and Correctness Proofs for Portions of the MSX Ada Software" from T. Menas, J. Bouler, and J. Doner, authors and SDVS researchers at The Aerospace Corporation. This document is to be given open and public distribution as an Aerospace Technical Report, ATR-93(3778)-5. I have examined this document and, in my opinion as COR for this unclassified research, the report is also unclassified and will not be detrimental to NSA's interest if released as requested. This report will also be reviewed and approved/disapproved for publication release by the MSX Pentagon's point-of-contact, LCOL Bruce Guilmain.

## Abstract

The Midcourse Space Experiment (MSX) is a Strategic Defense Initiative Organization program whose primary purpose is to conduct tracking event experiments of targets/phenomena in midcourse.

In this report we give a detailed account of the SDVS verification of a modified portion of the MSX tracking processor software. We present a functional overview of this part of the software, discuss and fully annotate our modifications to it, list the SDVS enhancements implemented during the course of the project, and present a proof of correctness of a simple but nontrivial specification.

## Acknowledgments

We are especially indebted to Richard Waddell and Shane Hutton of the Johns Hopkins University Applied Physics Laboratory for their help in discussions of issues raised in this report. We are also grateful for the help given to us by Mark Bouler, Ivan Filippenko, Beth Levy, David Martin, and Leo Marcus of The Aerospace Corporation.

# 1 Introduction

The purpose of this report is to document a 1993 joint project between The Aerospace Corporation (Aerospace) and the Johns Hopkins University Applied Physics Laboratory (JHU/APL) to verify a portion of the Midcourse Space Experiment (MSX) spacecraft tracking processor software (the target software) using SDVS. The project consisted of three major parts: (1) enhancements to SDVS, primarily to the SDVS Ada translator and to the SDVS proof language; (2) modifications to the target software required by the SDVS Ada translator, and (3) proofs of and specifications for the modified target software.

Although we will give a very brief overview of the MSX software we are attempting to verify, we assume that the reader is acquainted with [1]. Detailed accounts of the tracking processor design and software are given in [2] and [3]. The target software builds and processes application-level messages from serial digital commands relayed from the command processor to the tracking processor. There are eleven types of application-level messages. One of these, the data-structure memory-load application message (data-structure message, for short), can modify up to 109 tracking parameters. At the present time only 61 of these 109 parameters are specified; the others are for future use. The number of commands that are required to form a data-structure message is a function of the type of tracking parameter that the data-structure message modifies. Once built, the data-structure message is stored in EEPROM, RAM, or both. Our goal was to verify that the data-structure messages are built according to their specification. The specifications for data-structure messages are described in [4].

The MSX software is written in Ada and in 1750A assembly.<sup>1</sup> The heart of the target software consists of the three Ada tasks – BUILD, PROCESS\_MSG, and MANAGE\_MSG\_RETRIEVAL – in the package APP\_MSGS, and the interrupt-driven Ada procedure CMD\_IN\_HANDLER in the package SERIAL\_DIG\_CMDS. When an interrupt occurs signaling that a command is ready to be retrieved from a designated serial port, CMD\_IN\_HANDLER services the interrupt by retrieving the command and storing it in a command buffer. For an infinite number of times, if the command buffer is not empty, BUILD retrieves the command buffer, constructs application-level messages from these commands, places them in a circular message queue, and waits for a rendezvous with MANAGE\_MSG\_RETRIEVAL. Also for an infinite number of times, if the message queue is not empty, PROCESS\_MSG will rendezvous with MANAGE\_MSG\_RETRIEVAL to retrieve and process a message from the message queue. It stores data-structure messages in EEPROM, RAM, or both. As its name indicates, MANAGE\_MSG\_RETRIEVAL synchronizes the other two tasks.

The three tasks and the interrupt-driven procedure are essentially four tasks. It is important to note two facts: (1) the target software does not include a main program (or scheduler) to execute the tasks and the interrupt-driven procedure, and (2) SDVS does not currently handle Ada tasking. As a consequence, we translated the tasks into procedures and embedded these procedures in a program specifying an order of their execution. However, the translation of the tasks into procedures altered an important aspect of their executions;

---

<sup>1</sup>We are focusing on the software written in Ada. SDVS has the capability to verify programs written in a subset of 1750A assembly language as well, but this was not done in the current effort.

they could no longer be interleaved. Their execution as procedures, which is determined by the program, is one of the many possible execution sequences for the tasks. But the specification of the end result, namely that an infinite sequence of commands be processed into a corresponding infinite sequence of messages, remained the same for both the original and the modified MSX software.

Thus, Aerospace wrote the scheduler for the procedures that were tasks in the original software. Furthermore, we had to alter these procedures in various ways; these changes are explained in Section 4 and documented (statement by statement) in the actual modified target software listed in Appendix A. Some of the changes are equivalent to the original MSX code and some are not. We did not verify the correctness of the original code. However, we verified certain properties of the modified code that should also describe the original code; if the modified code did not satisfy the properties, then the original code would not have satisfied the properties. As a pragmatic consideration, if the modified code had not satisfied the properties, then, using the specifications, we could have constructed the appropriate test cases to demonstrate that the original code is incorrect. There is a range of possibilities in applying formal methods: e.g. formal specification and no proof, specification with hand-proof, specification with automated proof, etc. The MSX application was intended to stress our current SDVS capabilities by applying formal methods where possible, and it has been very useful for this. We worked with about 1000 lines of Ada code and tried to keep the modified version as close as possible to the original. The modified version of the code builds and processes messages, but without concurrent processes and a few other Ada constructs.

Section 2 presents a chronology of the MSX verification project using SDVS. After selecting the target software, we "walked through" the code to study it and itemize the Ada constructs not handled by the SDVS Ada translator. We also analyzed the parts of the code that interface with 1750A assembly language and the "intrinsic" functions supplied by the Tartan compiler, which is used for the compilation of the MSX software. The walk-through and the correspondence between Aerospace and JHU/APL were instrumental in the discovery of two errors in the target software.<sup>2</sup> After this initial phase of the project, we began the task of verification. Our approach was to provide proofs of correctness for increasingly complex situations. For our purposes, a correctness proof involves a program, a condition on its input (the input condition), and a specification relating the input to the output (the output condition). Complexity arose primarily from the generality of the scheduler and the type of input allowed by the input condition.

Section 3 discusses the enhancements we made to SDVS for the verification project, and Section 4 discusses modifications we made to the target software.

Section 5 presents some of the details of the proofs. The proofs appear in Appendix B. The scheduler that we wrote for `CMD_IN_HANDLER`, `BUILD` and `PROCESS_MSG` limits drastically the executions it encompasses; that is, the situations that arise in these executions, although possible, are really quite simple. For example, in every one of the allowed executions, the message queue is either empty or contains exactly one message, and the command buffer cannot be already full when another command is to be buffered. Thus, the message queue

---

<sup>2</sup>We note that at the time the errors were discovered, JHU/APL had not tested the code extensively.

can never overflow, and commands can never be lost. If there are any errors in the target software, one would expect them to be in precisely these boundary situations. It is really quite simple to write a scheduler that allows these boundary conditions to occur. We were forced to write this simple scheduler, because a proof of correctness for a more general scheduler would have been too difficult to construct in the time allotted for the one-year verification project. However, we think it is possible in SDVS to prove correctness for more general schedulers.

In Section 6 we discuss and present results from an approach involving the offline characterization capability of SDVS, which we think would facilitate proofs of correctness for more general schedulers. An approach to the verification effort using offline characterization would also reduce the size of proofs and the storage required for them, probably allowing the user to prove the correctness of the four large messages that we were unable to prove because of storage and time considerations.<sup>3</sup>

Offline characterization allows one to prove in SDVS an *adalemma* for a subprogram of a main program characterizing the results of the execution of the subprogram in a specific environment. It is, in fact, a proof of correctness for the subprogram. Instead of symbolically executing a subprogram when it is called in the SDVS execution of the main program, one may apply the *adalemma* for the subprogram and bypass its execution. This approach saves time and storage in a proof of correctness of a main program in which there are repeated calls to the subprogram. It also has the advantage of modularizing long proofs.

Section 7 contains our conclusions on the 1993 MSX verification project using SDVS.

---

<sup>3</sup>This verification project ended in fiscal year 1993.

## 2 Chronology of the MSX Verification Experiment

In this section we highlight the chronology of the 1993 MSX verification project using SDVS. We first note that many of the tasks constituting the project occurred throughout fiscal year 1993 and some tasks were done concurrently. For example, the enhancements to SDVS necessitated by the project continued throughout its duration, as was the fixing of SDVS bugs not previously detected.

We first studied the documentation for the tracking processor software (reports [2], [3] and [4]) and then looked at the actual code. In our walkthrough we examined 18 library units that fell either in the area or on the periphery of our target software and noted the following:

- (i) the library units and, specifically, the parts (targets) thereof needed in the building or processing of data-structure messages;
- (ii) the Ada constructs in the targets not handled by the SDVS Ada translator;
- (iii) the targets whose bodies were written in 1750A assembly code; and
- (iv) the nonstandard Ada function targets provided by the Tartan compiler (some of the "intrinsic" functions).

The part of the MSX code we selected for verification was chosen partially because of its importance to the MSX experiment as a whole. In the process of selecting the targets, we had to select, for our purposes, two demarcation points in the software: the point at which the input stream of commands begins and the point at which the writing of data-structure messages to EEPROM ends. The first selection was easy: the input stream of commands begins at the servicing of an interrupt by `CMD_IN_HANDLER`.

The second selection was only slightly more difficult. `PROCESS_MSG` processes all application-level messages. If the message is a data-structure message and is to be written in EEPROM, it calls `EEPROM_DATA.STORE_DATA_STRUC_IN_EEPROM`.

Although `STORE_DATA_STRUC_IN_EEPROM` has an Ada body, this body repeatedly calls subprograms written in 1750A assembly. For this reason, we decided to consider that the messages have been written to EEPROM at the call to `EEPROM_DATA.STORE_DATA_STRUC_IN_EEPROM`.

The walkthrough determined our real target software: the targets within the two points of demarcation and any other part of the Ada code they required.

We partitioned the Ada constructs of item (ii) above into two groups: (1) those we would add to the SDVS Ada translator, and (2) those we would replace by equivalent Ada constructs (for example, hexadecimal literals by decimal literals) or simply replace by nonequivalent constructs (for example, tasks by procedures). We then started to implement the constructs in the first group into the SDVS Ada translator and made the appropriate modifications to the code for the constructs in the second group.<sup>4</sup>

---

<sup>4</sup>These are described in Sections 3 and 4 of this report.

In Section 4 we discuss the targets written in 1750A assembly and our handling of them. In a few cases, we wrote simple Ada code for their bodies that altered their functionality. For example, our version of the CHECK\_PARITY function simply returns the boolean value *true*, whereas the original function returns either *true* or *false*, depending on the parity of the object to which it is applied. This change in the function alters the behavior of the main program. However it does not alter the behavior of the main program under the assumptions that all inputs have good parity, which is, in fact, one of our assumptions.

Common instances of calls to routines written in 1750A assembly language were calls to MEMORY\_MANAGER.CONV\_TYPE to convert from one type to another. We substituted these calls by explicit Ada type conversions: JHU/APL did not use these type conversions, because they were not handled properly by the Tartan compiler.

The actual MSX software is compiled at JHU/APL by the Tartan compiler. To test the target code using the Verdex Ada compiler available at Aerospace, we wrote Ada programs for the target “intrinsic” functions provided by the Tartan compiler: AND\_I, AND\_WORD, AND\_BYTE, and OR\_I. In the final SDVS correctness proofs, we characterized these functions by adalemmas. We used the Verdex compiler to test our modifications for syntactic correctness at every step of the modification process. In fact, we also tested several versions of the original code by executing it with various inputs. These versions were not identical to the original code because we replaced the routines that were written in 1750A assembly language, and we provided bodies for the Tartan-supplied “intrinsic” functions. But, we were able to test versions that were close to the original; for example, we were able to test a version with the original tasks.

Once we made the modifications and added the capability to translate subtypes to the SDVS Ada translator, we made our first attempt to translate and execute the target code in SDVS. We were immediately beset by a great number of heretofore undetected bugs in SDVS. SDVS had never been stressed with such a large Ada program before. We estimate that more than half of our time on this project was spent in fixing bugs or in attempting to deal with time and storage problems. As yet, the latter are not totally resolved.

After the bugs were corrected, we were able to complete a proof of correctness in SDVS of a program processing exactly three commands. The scheduler first made three calls to CMD\_IN\_HANDLER, then a call to BUILD, and finally a call to PROCESS\_MSG. The input condition asserted that the input consisted of three commands encoding an “AP propagation time” data-structure message to be written in EEPROM. The output condition asserted that the message stored in EEPROM corresponded, in a manner stipulated by the MSX documentation, to the input commands. Even for such a minor proof, the SDVS proof trace was over 350 pages long.

We next completed the *inf\_seq\_of\_2\_msg\_types* proof. Its input condition specified an input consisting of an infinite sequence of blocks of commands, each block encoding one of two types of data-structure messages: an “AP propagation time” message (message ID 10) or a “filter loss of track rules” message (message ID 22). In an infinite cycle, the scheduler called CMD\_IN\_HANDLER precisely the number of times needed to retrieve the next block from the input, then BUILD, and finally PROCESS\_MSG. The output condition asserted that

for each block of commands in the input, there is a message in the output corresponding to the input block in the manner stipulated by the MSX documentation. Furthermore, the correspondence of blocks of commands to messages is one-to-one, onto, and order-preserving.

It would seem that *inf\_seq\_of\_2\_msg\_types* could be trivially generalized to a proof whose input condition specifies an input consisting of an infinite sequence of blocks of commands, each block encoding *any* one of the 61 data-structure messages and whose output condition is amended in the obvious way. (For future reference, we refer to this proof as the "*inf\_seq\_of\_61\_msg\_types*" proof.) However, our attempts to complete *inf\_seq\_of\_61\_msg\_types* were thwarted by the amount of time required for its completion: the system on which we ran it never stayed up long enough to complete it. We estimated it would take at least seven days for the proof to terminate.

The major problem is that in proving that the *n*th block of commands is processed correctly, each of the 61 possible cases for this block must be considered separately (at least in our approach). Each case adds to the execution time of the proof. One of our solutions was to run many separate but similar proofs. In each proof we considered only a few of the cases for the *n*th block of commands, proved that one case, and deferred the proof for the other cases. But we ran into a problem. Because four of the messages were unusually long, the correctness proof for each one of these messages required more storage than that allowed by the SDVS image (about 70 megabytes) and even more storage than that allowed by the SDVS image we created specifically for the MSX verification project (300 megabytes). We were thus unable to verify the correctness for these four messages.

In our attempt to execute the *inf\_seq\_of\_61\_msg\_types* proof, we had to implement three new proof rules in SDVS: *repeat*, *loop*, and *if*. These were necessitated by the sheer size of the proof and are discussed in the next section. As we said in the previous page, we were never able to complete *inf\_seq\_of\_61\_msg\_types*, because the system never stayed up long enough for us to complete it. But we were able to complete 57 of the cases in separate proofs.

Towards the latter part of the project, we realized that many of our time and storage problems would be solved if we proved adalemmas for some of the key subprograms in BUILD and in CMD\_IN\_HANDLER. We were able to complete adalemmas for two of the main procedures in BUILD, and these are described in Section 6.

### 3 Enhancements Made to SDVS for the MSX Verification Project

There are two main types of enhancements we made to SDVS for the MSX verification project: enhancements to the SDVS Ada environment and the addition of three proof commands not specific to that environment.

We first list and comment on the SDVS Ada environment enhancements. The first five in the list are standard Ada constructs (see [5]), whereas the others are improvements to the SDVS Ada proof environment.

(i) Integer subtypes:

One of the important aspects of the addition of integer subtypes to the Ada translator is that an assignment to an integer subtype object is allowed by SDVS only if the value assigned to the object is within the range of the subtype.

(ii) Integer definition types:

The restrictions on assignment are similar to those for integer subtypes: an assignment to an integer definition type object is allowed by SDVS only if the value assigned to the object is within the range stipulated by its type definition.

(iii) Type conversions:

These conversions are allowed only for integer numeric types (integer types and integer definition types).

(iv) UNCHECKED\_CONVERSION:

We have added UNCHECKED\_CONVERSION only for integer numeric types.

(v) Length representation clauses:

These have been implemented only for integer numeric types. The length stipulated for these types must be great enough to represent the type's stipulated range.

(vi) Markpoints:

These are used to mark Ada statements. We have added this marking capability to SDVS to allow the user to *go* (execute symbolically) to a specific marked point in the program. The user sets a mark in an Ada comment line just before the statement being marked, using the notation "--@" (no spaces):

```
--@ foo
x := 1;
```

During symbolic execution, this yields "*pc* = *at*(foo)" (where "*pc*" is the program counter) at the point where the state delta(*s*) representing the marked statement become usable. Despite this fact, the user will not see "*#pc* = *at*(foo)" appear explicitly in the postcondition of the previously applied state delta. Any Ada statement can be marked. Note that the marked program remains acceptable to an Ada compiler; the marked points are treated as comments by Ada compilers. A mark can be turned

into a regular (uninterpreted in SDVS) comment simply by inserting a space between the "--" and the "@", or by beginning the whole line with an extra pair of hyphens (even a single hyphen will do, so long as it's not followed by a space).

(vii) *adasubprogenv*:

This query command is quite useful in connection with the Ada offline characterization facility. It displays the mapping of fully qualified program names to uniquely qualified place names for all places constituting the environment for the proof of an *adalemma* about a subprogram.

(viii) Improved handling of Ada array constants:

The initialization of constant arrays in SDVS requires inordinately large storage and is extremely time-consuming. We had to add special Lisp code to handle these initializations. This addition is experimental and is not incorporated into SDVS 12. In our proof, we load the file "array\_constant.lisp" to perform the initialization of constant arrays. These enhancements will be added to a future version of SDVS when the implementation is more robust.

(ix) Bugs:

Some of the things we have been calling "bugs" were in fact restrictions on the SDVS Ada translator of which we were not aware. For example, the translator did not allow the following declaration in the package SERIAL\_DIG\_CMDS:

```
procedure RET_CMD_BUF_AND_STATUS
  (Cmd_Buf           : out CMD_BUF_TYPE;
   Cmd_Status_Buf    : out CMD_STATUS_BUF_TYPE;
   Cmd_Count         : out INTEGER;
   FIFO_Not_Empty_Count : out INTEGER;
   IO_Status_Word     : out GLOBAL_TYPES.WORD;
   Lost_Cmd          : out BOOLEAN);
```

The reason was that the package also contained the object declaration  
Cmd\_Buf : CMD\_BUF\_TYPE;

We removed limitations such as this as they arose in the course of the project.

In the course of our proofs, we realized that the addition of three new proof commands to SDVS would obviate a lot of repetitive work. These three commands are *loop*, *repeat*, and *if*. Since we have not tested them extensively, we have not added them to SDVS 12. These commands enabled us to write a "meta-level" proof; instead of writing 57 subproofs for the 57 cases in the MSX proof, we wrote one meta-level proof for all these cases.

The *loop* command has the syntax "UNTIL <condition> WITH <proof-name>." It is effectively a generalization of the *go* command, except that instead of simply executing *apply* commands until <condition> is true, it repeatedly interprets (executes) the proof <proof-name> until the condition is true.

The *repeat* command has the syntax “<proof-name> ITERATING ON <iteration-variable> FROM <lower\_bound> TO <upper\_bound>.” It allows the user to write a parameterized proof (that is, a proof which involves the <iteration-variable>) and then to execute the proof <proof-name> successively with each value in the range from <lower\_bound> to <upper\_bound> substituted for <iteration-variable>. The formulas <lower\_bound> and <upper\_bound> must simplify to integer values.

The *if* command has the syntax “IF <condition> THEN <proof-name>.” This command interprets the proof <proof-name> if <condition> is true, and does nothing otherwise.

## 4 Modifications to the Code

In this section we list the extensive modifications we made to the target software. The great majority of these modifications were necessary either because the SDVS Ada translator does not handle Ada tasking or because parts of the target software were written in 1750A assembly. The entire program appears in Appendix A. We have marked every statement that we deleted or replaced in the `SERIAL_DIG_CMDS` and `APP_MSGS` packages.

### 1. Ada *with* clause:

Our original intent was to implement the *with* clause into the SDVS Ada translator. During our work on the design of the implementation, we realized the implementation would take a great deal of time that would be better spent on the other Ada constructs, since we could achieve part of the effect of the *with* clause by simply ordering the packages in the main program in the “right” order. In many cases, if the *with* clause were not used when needed in the original software, it would not be possible to compile the packages. We do not claim that the way we dealt with this clause is not prone to error. However, we don’t think our solution allowed us to prove the correctness of code (under the circumstances stipulated by our input condition) that was in fact incorrect.

### 2. Ada *tasks*:

We have probably belabored this point: SDVS does not currently handle tasking. We declared the tasks as procedures and deleted any Ada construct that is specific to tasking. Thus, we deleted the simple loops in the three procedures that were originally tasks as well as the pertaining exits. A simple loop requires an infinite execution of its body, unless an exit in the loop intervenes. Thus, the purpose of a simple loop in a task is to ensure that the task executes infinitely often. Once we changed a task to a procedure and deleted the simple loop in its body, the procedure’s infinite execution could be ensured only by the scheduler we developed. We had to delete the simple loops in these procedures, because otherwise, once one of these procedures was called by the scheduler, it would never relinquish control of the execution to the others. The scheduler now performs the function of the simple loops, that is, to execute the procedures repeatedly.

We also deleted the exception handlers: they were used only for tests involving the tasks.

We deleted calls to the Tartan-supplied `ARTCLIENT` that is used in the code to enter and leave critical sections of the tasks and the interrupt-driven procedure.

### 3. Ada *pragma*:

We deleted all pragmas. As we noted in [1], pragmas are instructions to the compiler and are generally not meant to change the semantics of an Ada program. In almost all instances, the pragmas in the target software involved either tasking or interfacing with the 1750A assembly code. (The pragmas we deleted are *elaborate*, *priority*, *pack*, *Foreign\_Body*, and *Linkage\_Name*.)

#### 4. INTRINSICS and INTRINSIC\_FUNCTIONS:

We deleted all references to the Tartan-supplied INTRINSICS package. The INTRINSIC\_FUNCTIONS package consists of generic instantiations of generic functions appearing in the INTRINSICS package. We characterized the instantiations we needed in the target code (AND\_I, AND\_WORD, AND\_BYTE, and OR\_I) by adalemmas.

#### 5. Embedded calls to 1750A code:

We enumerate and comment upon the instances of calls to 1750A assembly subprograms in target code.

- In CMD\_IN\_HANDLER, a call is made to the ASM.UTILITY.CHECK\_PARITY function to obtain the parity of a command. We provided a trivial Ada body for the parity function that always returns good parity (*true*). This solution is not entirely satisfactory because it does not allow the possibility of checking the code to determine what happens if a command does not have good parity. Our original intent was to give an offline characterization of CHECK\_PARITY, allowing the possibility of returning *false* in certain cases. We did not have the time to do this.
- CMD\_IN\_HANDLER services an interrupt indicating that there is a command to be retrieved from the FIFO buffer. It obtains the command by the following call:

```
MEMORY_MANAGER.READ_FIFO(Cmd_In_FIFO_Addr,  
                           Cmd_Unpacked'address,  
                           Cmd_Size);
```

(MEMORY\_MANAGER is written in 1750A assembly.) We chose this to be the point at which the target code obtains input, and substituted the above call to MEMORY\_MANAGER.READ\_FIFO by a "for" loop that gets four bytes for the command from the standard input.

- In PROCESS\_MSG, a call is made to MEMORY\_MANAGER.CONV\_TYPE to assign the value of New\_App\_Msg(2) (an integer) to Temp\_Word\_1 (a word). The body of CONV\_TYPE is written in 1750A. We replaced this call by a type conversion: `Temp_Word_1 := GLOBAL_TYPES.WORD(New_App_Msg(2));`

In MANAGE\_MSG\_RETRIEVAL, another call is made to MEMORY\_MANAGER.CONV\_TYPE to convert each word stored by an array of words to an integer. We replaced this call by the following Ada type conversion:

```
for index in 1 .. Num_Words_Curr_App_Msg loop  
  App_Msg_Out(index) := INTEGER(App_Msg_Q(Q_Head)(index));  
end loop;
```

- Again, in CONTINUE\_BUILD, a call is made to MEMORY\_MANAGER.CONV\_TYPE to convert an integer to a word. We replaced this call by an Ada type conversion.

#### 6. Hexadecimal Notation:

We have replaced all hexadecimal literals by equivalent decimal literals.

7. Two-dimensional arrays:

We have replaced all two-dimensional arrays with one-dimensional arrays of one-dimensional arrays.

8. Ada *others* initialization construct:

Originally, we intended to add the *others* initialization construct to the SDVS Ada translator, but we did not have time to do it. However, in every case it is used in the target code, it is used to initialize arrays or records with values that are never actually used within this code. We simply deleted these initializations. In SDVS, these objects would simply have unknown symbolic values initially. Since nothing is known about these values, nothing could be proved from the assumption that they are unknown.

9. Ada *WRITELN* and *WRITESTRING*:

We deleted all *WRITELN* and *WRITESTRING* constructs, which are not part of the standard Ada definition but are accepted by the Tartan compiler. These constructs appear in the target software for testing purposes only.

10. Ada *POSITIVE* type:

This predefined subtype is used in the package *CMDS\_TYPES*. We replaced these occurrences by equivalent code. For example, we replaced the declaration

```
subtype INDEX_SUBTYPE is POSITIVE range 1..App_Msg_Max;
```

by the declaration

```
subtype INDEX_SUBTYPE is INTEGER range 1..App_Msg_Max;
```

11. Unconstrained array types:

There is one unconstrained array type, *APP\_MSG\_OUT\_TYPE*, defined in *CMDS\_TYPES*. We redefined this type to be a constrained array type with the maximum range possible:

```
App_Msg_Max          : constant INTEGER := 80;
--SDVS comment: The predefined type POSITIVE is not implemented in SDVS.
--SDVS delete: subtype INDEX_SUBTYPE is POSITIVE range 1..App_Msg_Max;
  subtype INDEX_SUBTYPE is INTEGER range 1..App_Msg_Max;--SDVS replace
--SDVS comment: SDVS does not currently handle unconstrained array types.
--SDVS delete (unconstrained array): type APP_MSG_OUT_TYPE is
--SDVS cont:      array (INDEX_SUBTYPE range<>) of INTEGER;
  type APP_MSG_OUT_TYPE is array (1 .. App_Msg_Max) of INTEGER; --SDVS replace
Load_Msg_Max         : constant INTEGER := 127;
type LOAD_MSG_TYPE    is array (1..Load_Msg_Max) of INTEGER;
```

12. Array slices

In *PROCESS\_MSG*, a slice of the array *New\_App\_Msg* is written to EEPROM by the call

```

-- Strip off New_App_Msg(1) which contains opcode,
-- the contents of data structure (including checksum) is
-- stored in New_App_Msg(2) thru (Data_Struc_Length+1).
--New_App_Msg(1..Data_Struc_Length) :=
--
--      New_App_Msg(2..Data_Struc_Length+1);
EEPROM_DATA.STORE_DATA_STRUC_IN_EEPROM
      (New_App_Msg(2..Data_Struc_Length+1),
       Data_Struc_ID,
       Data_Struc_Length);

```

The slice is, in fact, the entire message. Since the SDVS Ada translator does not handle array slices, we have replaced the above call by

```

EEPROM_DATA.STORE_DATA_STRUC_IN_EEPROM
      (New_App_Msg,
       Data_Struc_ID,
       Data_Struc_Length);

```

The procedure STORE\_DATA\_STRUC\_IN\_EEPROM, whose body we wrote, simply outputs the array slice from 2 to Data\_Struc\_Length + 1.

## 5 Proofs for an Infinite Sequence of Data Structure Messages

We have finished a proof that `MSX_PROGRAM_FINAL_VERSION`, a suitably modified version of the original program, correctly processes infinite sequences of 57 of the 61 data-structure messages. This section contains a discussion of the proof and Appendix B contains the complete proof.

Before we discuss the proof itself, we must first note a few facts about input and output in SDVS for Ada programs in general, and input and output in the `MSX_PROGRAM_FINAL_VERSION` program in particular. We also describe the scheduler for this program, i.e., its body, in the following section.

### 5.1 Preliminaries to program input and output

For each program translated by the SDVS Ada translator, SDVS declares two objects, *stdin* and *stdout*, to be one-dimensional unbounded arrays of polymorphic type. *Stdin* is the standard input array: every value input via a call to the function *get* is obtained from the standard input array. The position in the array of the item obtained is determined by the order of the calls. For example, if *get(x)* is the first call to *get* in a program, then object *x* is assigned the value stored in *stdin[1]*. The standard input array is constant throughout the execution of the program. The standard output array, *stdout*, has a similar function, although unlike *stdin* it changes during the execution of a program when the function *put* is called. In SDVS, assertions about the input or the output of a program are assertions about the current values of the standard input array and the future values of the standard output array.

In the design of the target software, a byte is eight bits long; a word is sixteen bits long; and a command consists of two words. In the actual Ada code, bytes and words are represented by integers constrained to specific ranges. Commands are represented either as arrays of four bytes or as records with four fields, each field corresponding to one byte. Although bytes (words) have an integer parent type, they encode sequences of zeros and ones that are eight (sixteen) bits long. For example, if the integer value of the byte *B* is seven, then *B* encodes (i.e., contains) the bit sequence `< 00000111 >`.

In the target software, `CMD_IN_HANDLER` obtains a command by the call

```
MEMORY_MANAGER.READ_FIFO(Cmd_In_FIFO_Addr,  
                           Cmd_Unpacked'address,  
                           Cmd_Size);
```

`Cmd_Unpacked` is an array of four bytes, and `MEMORY_MANAGER.READ_FIFO` is a procedure with a body written in 1750A assembly code. We have substituted this call by the following:

```

    for i in 1 .. 4 loop
        get(cmd_unpacked(i));
    end loop;

```

Thus, every call to CMD\_IN\_HANDLER gets four elements (bytes) from the standard input array.

In the target software, PROCESS\_MSG “writes” a message to EEPROM by the call

```

EEPROM_DATA.STORE_DATA_STRUC_IN_EEPROM
    (New_App_Msg(2..Data_Struc_Length+1),
     Data_Struc_ID,
     Data_Struc_Length);

```

New\_App\_Msg, an array of words, is the processed message.

In our modified code, we have changed this call to

```

EEPROM_DATA.STORE_DATA_STRUC_IN_EEPROM
    (New_App_Msg,
     Data_Struc_ID,
     Data_Struc_Length);

```

and decided to stop the message processing at this step.<sup>5</sup> At this point, the message has been built; we have changed the body of STORE\_DATA\_STRUC\_IN\_EEPROM so that it simply outputs the message as follows:

```

procedure STORE_DATA_STRUC_IN_EEPROM
    (Array_Of_Words      : in    CMDS_TYPES.APP_MSG_OUT_TYPE;
     Data_Struc_ID       : in    INTEGER;
     Data_Struc_Length   : in    INTEGER) is
begin
    for i in 2 .. Data_Struc_Length + 1 loop
        put(Array_Of_Words(i));
    end loop;
end STORE_DATA_STRUC_IN_EEPROM;

```

---

<sup>5</sup>We decided to verify the load to EEPROM up to this point only, since the message has been built at this point, and the machinery for the “write” to EEPROM has been initiated. The execution that follows in the original MSX software shortly leads to the invocation of procedures written in 1750A code.

Thus every call to `STORE_DATA_STRUC_IN_EEPROM` puts a message in the standard output array, word by word.

Having discussed the points at which calls to *get* and *put* occur in the modified software, we may now present the order of execution of the modified interrupt-driven procedure and the modified tasks. The execution order is determined by the body of `MSX_PROGRAM_FINAL_VERSION`:

```
begin
  --@ loop_begin

  loop
    SERIAL_DIG_CMDS.COMD_IN_HANDLER;
    for i in 2 .. APP_MSGS.RET_MSG_LENGTH(SERIAL_DIG_CMDS.RET_MSG_ID) loop
      SERIAL_DIG_CMDS.COMD_IN_HANDLER;
    end loop;
    APP_MSGS.BUILD;
    APP_MSGS.PROCESS_MSG;
  end loop;

end MSX_PROGRAM_FINAL_VERSION;
```

Each iteration of this loop accomplishes four things. In order, they are as follows:

- The first command of the next message is read (call to `SERIAL_DIG_CMDS.COMD_IN_HANDLER`).
- The remaining commands of the next message are read (*for* loop).
- The data for the newly read message are extracted and put into a new format consisting of words (call to `APP_MSGS.BUILD`).
- These words are output (call to `APP_MSGS.PROCESS_MSG`).

A property of this loop crucial to the proof is that it processes exactly one message block on each iteration.

## 5.2 The correctness assertion for `MSX_PROGRAM_FINAL_VERSION`

The correctness assertion for `MSX_PROGRAM_FINAL_VERSION` is the state delta *infinite\_sequence\_data\_structure\_messages.sd*. It is the formal equivalent of the informal correctness assertion “the Ada program `MSX_PROGRAM_FINAL_VERSION` correctly partitions and reformats an infinite input stream of bytes into its constituent messages”.

```

(defsd infinite_sequence_data_structure_messages.sd
  "[sd pre: (formula(finale.sd),
    formula(input_places_disjoint.sd),
    formula(output_places_disjoint.sd),
    ada(msx_program_final_version.a),
    formula(checksum_first_k_bytes_message_n_definition),
    formula(checksum_definition),
    formula(msg_in_lh_definition),
    formula(msg_out_lh_definition),
    formula(msg_input_begins_at_definition),
    formula(msg_output_begins_at_definition),
    formula(allowed_message_ids),
    formula(input_condition))
  comod: (all)
  mod: (all)
  post: (formula(output_condition)) ]")

```

The first three formulas in the precondition of this state delta (*finale.sd*, *input\_places\_disjoint.sd*, and *output\_places\_disjoint.sd*) are state deltas that are used in the proof of *infinite\_sequence\_data\_structure\_messages.sd*. Each of these three state deltas has been proved in SDVS, and their proofs are included in Appendix B. Usually such state deltas are written as lemmas and do not appear in the precondition, but these formulas contain quantifiers and the current SDVS implementation cannot handle lemmas that contain quantifiers. In normal circumstances, we would have simply proven these facts in the same SDVS session with the main proof, but the way we conducted the final proof (explained in more detail later) meant that we would have had to run the proofs of these state deltas (which take a significant amount of time) many times. Since we were already concerned about the amount of time the main proof was going to take, we decided to prove these once and include them in the precondition of the correctness assertion rather than reprove them many times.

The next part of the precondition (*ada(msx\_program\_final\_version.a)*) is a predicate that corresponds to the program `MSX_PROGRAM_FINAL_VERSION`. The formula *input\_condition* in the precondition specifies the input condition for this program: it depends on the formulas *checksum\_first\_k\_bytes\_message\_n\_definition*, *checksum\_definition*, *msg\_in\_lh\_definition*, *msg\_out\_lh\_definition*, *msg\_input\_begins\_at\_definition*, and *allowed\_message\_ids*. The formula *output\_condition* in the postcondition specifies the output condition: it depends on the formulas *msg\_out\_lh\_definition* and *msg\_input\_begins\_at\_definition*.

The formula *allowed\_message\_ids* and those formulas whose names end in *\_definition* are used in the correctness assertion only to help define the input condition and output condition, and are strictly speaking unnecessary: that is, we could have written the correctness assertion without them. We feel, however, that they aid greatly in simplifying the proof and in making it understandable. In the next two subsections, we will discuss first the formulas used in the input condition, and then the formulas used in the output condition.

### 5.2.1 The input condition

In this subsection we will discuss in detail the input condition for the program. As mentioned earlier, the main formula used to specify the input condition is the formula *input\_condition* below (this formula is taken directly from page 146 in Appendix B).

```
(defformula input_condition
  "forall x (forall z (x ge 1 -->
    ; The first byte is always 1
    ((z = 1 --> .stdin[msg_input_begins_at(x) + (z-1)] = 1) &

    ; The second byte is always 2
    (z = 2 --> .stdin[msg_input_begins_at(x) + (z-1)] = 2) &

    ; The third byte is the message identifier
    (z = 3 --> .stdin[msg_input_begins_at(x) + (z-1)] = msg_id(x)) &

    ; As for the remaining bytes...
    ((4 le z & z le  msg_in_lh(x)) -->

      ; If it's the first byte of a command, it's an eight
      ((z mod 4 = 1 -->
        .stdin[msg_input_begins_at(x) + (z-1)] = 8) &

      ; Otherwise, we only know it's a byte
      (z mod 4 != 1 -->
        is.byte(.stdin[msg_input_begins_at(x) + (z-1)])))) &

    ; First checksum byte is the high bits of the checksum word
    ; for message x
    ((z = ((8 * msg_out_lh(x) - 2) / 3)) -->
      .stdin[msg_input_begins_at(x) + (z-1)] =
        high.bits(checksum(x))) &

    ; Second checksum byte is the low bits of the checksum word
    ; for message x
    ((z = ((8 * msg_out_lh(x) + 2) / 3)) -->
      .stdin[msg_input_begins_at(x) + (z-1)] =
        low.bits(checksum(x))))))"
```

This formula (in conjunction with other formulas) specifies an infinite sequence of data structure messages: the embedded comments show how it corresponds to the informal specification of a data-structure message given in [1]. Examination of this formula reveals that it depends on the macros *is.byte(x)*, *high.bits(x)*, and *low.bits(x)*, and on the functions

*msg\_input\_begins\_at*, *msg\_in\_lh*, *msg\_id*, and *checksum*. We will first explain the macros, then the functions *msg\_input\_begins\_at*, *msg\_in\_lh*, and *msg\_id*, and finally the function *checksum*. In the course of explaining these functions (and other functions used to define them), we will explain all of the functions in the precondition.

First the macros. The macro *is.byte(x)* is true when  $x$  is between 0 and 255, inclusive, false otherwise. The macros *high.bits(x)* and *low.bits(x)* are used to represent the most and least significant eight bits of a word, respectively.

We will now discuss those functions used in the input condition. To clarify the following discussion, we have provided Table 1, which illustrates the values of the functions for a message sequence whose first three messages in order have identifiers 22, 10, and 1. All of the constituent bytes of the first two messages, and the first six of the third, are shown in Table 1. This table also includes a condensed display of the  $n$ th message to illustrate the values of these functions for input value  $n$ .

The function *msg\_input\_begins\_at* plays an important role in specifying the input. As the name suggests, the value of this function at  $x$  is the location of the byte where the  $x$ th message begins. Thus the first byte of the  $x$ th message is *.stdin[msg\_input\_begins\_at(x)]*, the second is *.stdin[msg\_input\_begins\_at(x) + 1]*, etc. This function is defined in the following way:

```
(defformula msg_input_begins_at_definition
  "forall x (msg_input_begins_at(1) = 1 &
    ((x gt 1) -->
      (msg_input_begins_at(x) =
        msg_input_begins_at(x-1) + msg_in_lh(x-1))))")
```

This definition is based on the observation that the first byte of the  $x$ th message is one plus the sum of the lengths of the preceding messages. We can see this by expanding the definition above at  $x$ :

$$\begin{aligned}
 \text{msg\_input\_begins\_at}(x) &= \\
 \text{msg\_input\_begins\_at}(x-1) + \text{msg\_in\_lh}(x-1) &= \\
 (\text{msg\_input\_begins\_at}(x-2) + \text{msg\_in\_lh}(x-2)) + \text{msg\_in\_lh}(x-1) &= \\
 &\vdots \\
 (\dots((1 + \text{msg\_in\_lh}(1)) + \text{msg\_in\_lh}(2)) + \dots + \text{msg\_in\_lh}(x-2)) + \text{msg\_in\_lh}(x-1)
 \end{aligned}$$

The function *msg\_in\_lh* used above is defined in the formula *msg\_in\_lh\_definition* on page 142 in Appendix B. This definition is based on the specification of the message input lengths as determined by the message identifier. The formula *msg\_in\_lh\_definition* employs the function *msg\_id(x)*, which as we can see from the formula *input\_condition* above, returns the same value at  $x$  as the message identifier for message  $x$  (i.e., the third byte of message  $x$ ). An important part of the input condition is the formula *allowed\_message\_ids* (given on

Table 1: Example Input Sequence

	Byte	Value
Block 1	1 ( $= \text{msg\_input\_begins\_at}(1)$ )	1
	2	2
	3	22 ( $= \text{msg\_id}(1)$ )
	4	$d_{1,1}$
	5	8
	6	$d_{1,2}$
	7	$\text{high.bits}(\text{checksum}(1))$
	8	$\text{low.bits}(\text{checksum}(1))$
Block 2	9 ( $= \text{msg\_input\_begins\_at}(2)$ )	1
	10	2
	11	10 ( $= \text{msg\_id}(2)$ )
	12	$d_{2,1}$
	13	8
	14	$d_{2,2}$
	15	$d_{2,3}$
	16	$d_{2,4}$
	17	8
	18	$\text{high.bits}(\text{checksum}(2))$
	19	$\text{low.bits}(\text{checksum}(2))$
	20	spare
Block 3	21 ( $= \text{msg\_input\_begins\_at}(3)$ )	1
	21	2
	22	1 ( $= \text{msg\_id}(3)$ )
	23	$d_{3,1}$
	24	8
	25	$d_{3,2}$
	$\vdots$	$\vdots$
Block $n$	$\text{msg\_input\_begins\_at}(n)$	1
	$\text{msg\_input\_begins\_at}(n) + 1$	2
	$\text{msg\_input\_begins\_at}(n) + 2$	$\text{msg\_id}(n)$
	$\text{msg\_input\_begins\_at}(n) + 3$	$d_{n,1}$
	$\text{msg\_input\_begins\_at}(n) + 4$	8
	$\text{msg\_input\_begins\_at}(n) + 5$	$d_{n,2}$
	$\vdots$	$\vdots$
	$\text{msg\_input\_begins\_at}(n) + \text{msg\_in\_lh}(n) - 1$	$\text{low.bits}(\text{checksum}(n))$ or spare
Block $n + 1$	$\text{msg\_input\_begins\_at}(n + 1)$	1
	$\vdots$	$\vdots$

page 141 of Appendix B), which constrains the value of  $msg\_id(x)$  (and hence the third byte of message  $x$ ) to be a legitimate message identifier.

Finally, the function *checksum* (defined on page 146 in the Appendix) represents the result of the program's calculation of a message's checksum. This function is defined with the help of two other functions: *sdvs\_xor\_word*( $x, y$ ), which corresponds to the Ada XOR\_WORD( $X, Y$ ) function; and *checksum\_first\_k\_bytes\_message\_n*( $n, k$ ), which uses the *sdvs\_xor\_word* function and represents the result of the checksum calculation on the first  $k$  words of the  $n$ th message.

The position of the checksum bytes is given in the formula *input\_condition* in terms of the function *msg\_out\_lh*. This function and the function *msg\_output\_begins\_at* are defined for output in the same way that *msg\_in\_lh* and *msg\_input\_begins\_at* are defined for input. We will discuss *msg\_out\_lh* and *msg\_output\_begins\_at* in the next section.

### 5.2.2 The output condition

The output condition for the correctness assertion is given by the formula *output\_condition* below:

```
(defformula output_condition
  "x ge 1 --> (forall z (( 1 le z & z le msg_out_lh(x))
    --> #stdout[msg_output_begins_at(x) +(z-1)]
      = mk.word(.stdin[msg_input_begins_at(x)
        + ((8 * z - 5) / 3)],
        .stdin[msg_input_begins_at(x)
        + ((8 * z - 1) / 3]])))")
```

This formally expresses the relationship between the input and output given informally in [1], which in brief may be stated “the output for a message is obtained by extracting the actual data bytes from the input for that message and forming them into words”. This formula depends on the macro *mk.word* and the functions *msg\_output\_begins\_at* and *msg\_out\_lh*. The macro *mk.word*( $x, y$ ) is a function that gives the integer value of a word whose high bits are the byte  $x$  and whose low bits are the byte  $y$ . This macro is used to capture succinctly the operation of “...forming them into words”, given in the quotation earlier in this paragraph.

As indicated earlier, the functions *msg\_output\_begins\_at* and *msg\_out\_lh* (defined on pages 145 and 144, respectively) are the analogues of *msg\_input\_begins\_at* and *msg\_in\_lh* for output. As with the input condition, for clarification we include a table (Table 2) of the output for the input given in Table 1. Comparing Table 1 and Table 2 shows that the input and output for the example sequence do in fact have the relationship stated in the quotation in the preceding paragraph, with the last word of the output for message  $n$  being the checksum for that message [i.e., *checksum*( $n$ )].

Table 2: Example Output Sequence

	Word	Value
Block 1	1 ( $= \text{msg\_output\_begins\_at}(1)$ )	$\text{mk.word}(2, 22)$
	2	$\text{mk.word}(d_{1,1}, d_{1,2})$
	3	$\text{checksum}(1)$
Block 2	4 ( $= \text{msg\_output\_begins\_at}(2)$ )	$\text{mk.word}(2, 10)$
	5	$\text{mk.word}(d_{2,1}, d_{2,2})$
	6	$\text{mk.word}(d_{2,3}, d_{2,4})$
	7	$\text{checksum}(2)$
Block 3	8 ( $= \text{msg\_output\_begins\_at}(3)$ )	$\text{mk.word}(2, 1)$
	9	$\text{mk.word}(d_{3,1}, d_{3,2})$
	$\vdots$	$\vdots$
Block $n$	$\text{msg\_output\_begins\_at}(n)$	$\text{mk.word}(2, \text{msg\_id}(n))$
	$\text{msg\_output\_begins\_at}(n) + 1$	$\text{mk.word}(d_{n,1}, d_{n,2})$
	$\vdots$	$\vdots$
	$\text{msg\_input\_begins\_at}(n) + \text{msg\_out\_lh}(n) - 1$	$\text{checksum}(n)$
Block $n + 1$	$\text{msg\_input\_begins\_at}(n + 1)$	$\text{mk.word}(2, \text{msg\_id}(n + 1))$
	$\vdots$	$\vdots$

### 5.3 The proof of `infinite_sequence_data_structure_messages.sd`

In this subsection we will talk about the proof of the state delta *infinite\_sequence\_data\_structure\_messages.sd*. We will present here the proof given in Appendix B (which is there presented in a “bottom-up” fashion) in a “top-down” style, proceeding from a high-level view of the proof through increasing levels of detail.

As we have mentioned before, `MSX_PROGRAM_FINAL_VERSION` has an infinite loop as its main body. Our proof strategy in the proof of *infinite\_sequence\_data\_structure\_messages.sd* (*main.proof* on page 197 of Appendix B) is to execute symbolically to the beginning of this loop and to then use loop induction. As is typical with loop induction, we chose a loop invariant weak enough to be proved after symbolically executing through the loop, but strong enough to imply the goal when the induction was finished. In our case, the invariant of the loop induction is the following:

```

      :
      :
comment  "Starting induction...",

induct on:      n
from:          1

```

```

to:          x + 1
invariants:
(
  ;Needed for covering information

  pcovering(.msx_program_final_version,old_universe),

  ;Variable values

  .build_in_progress = false,
  .cmd_count = 0,
  .lost_cmd = false,
  .app_msg_counter = 0,

  ;Queue variables and bounds

  .q_head
    = 1 + .q_tail mod .app_msg_q_size,
  .q_head ge origin(app_msg_q),
  .q_head
    le (origin(app_msg_q) +
        range(app_msg_q)) - 1,
  .q_tail mod .app_msg_q_size + 1
    ge origin(app_msg_q),
  .q_tail mod .app_msg_q_size + 1
    le (origin(app_msg_q) +
        range(app_msg_q)) - 1,

  ;State delta at beginning of loop

  formula(loopsd),

  ;Input/output counters are where they should be

  msg_input_begins_at(n) = .stdin\ctr,
  msg_output_begins_at(n) = .stdout\ctr,

  ;Output condition is true after execution of loop when
  ;n = x. This is stated in this way due to efficiency
  ;considerations (i.e., the more straightforward way
  ;introduces many new places - see report for more details).

  n = x + 1 --> formula(output_condition))

```

:

The crucial formula in the invariant above is the last one. When the loop induction is completed, the upper bound of the loop  $x + 1$  is substituted for  $n$  in this formula, and thus  $x + 1 = x + 1 \rightarrow \text{formula}(\text{output\_condition})$  is true after the induction is finished. It is then easy to proceed to the proof of  $\text{formula}(\text{output\_condition})$ . Instead of this formula, we originally tried  $\text{formula}(\text{output\_condition})$  with  $n$  substituted for  $x$ , but we found that using this in the invariant caused the prover to slow down significantly and we aborted the proof before it finished.

Whenever SDVS encounters a new place, it must add information to its database about whether changes to that place cause changes to any of the places already in the database. Both the operation of adding a new place to the database and the operation of checking to see what other places are affected when a given place is changed can be time-consuming when there are many places and some of the places are not known to be disjoint, i.e., changes to these variables may cause changes to other variables. Using  $\text{formula}(\text{output\_condition})$  with  $n$  substituted for  $x$  in the invariant of the `induct` command introduced elements of `stdin` and `stdout` that are not necessarily disjoint from elements of these arrays introduced earlier in the proof (specifically, via the postcondition of the correctness assertion, which is simply  $\text{formula}(\text{output\_condition})$ ) and thus was responsible for the proof proceeding slowly. The formula we actually used avoids this problem, as it contains exactly the same elements of `stdin` and `stdout` as  $\text{formula}(\text{output\_condition})$ .

As with any loop induction, there is a base case and a step case: these are handled in the main proof above by `base_case.proof` and `step_case.proof`, respectively. The base case proof is short and straightforward, as most of the goals are automatically proved by SDVS. The step case is proved by doing a case split on all possible values of  $\text{msg\_id}(n)$ , and then using the same meta-level proof `every_case.proof` in each case. Aided by the new proof commands `loop`, `repeat`, `if` (described in an earlier section) and `letq` (which allows quantified formulas to be given more meaningful names), we were able to write such a meta-level proof because of the similarity of the proof for each case.

After system crashes thwarted our attempts to complete the week-long proof, we decided that the full proof would be done in a number of separate SDVS runs rather than a single run. This was by done using different versions of `step_case.proof` (these begin on page 168 of Appendix B) when running the main proof. Each of these versions carries the proof through only for certain message identifiers and defers the cases for other message identifiers. For example, the first version of `step_case.proof` proves correctness for the case  $\text{msg\_id}(n) = 1$  and defers all the other cases. These versions cover all possible cases except for message identifiers 53, 54, 55, and 56. The messages with these identifiers are all substantially longer than any of the other messages, and because of the structure of the meta-level proof, the time and space requirements for each case vary directly with the length of the message treated in that case. SDVS ran out of storage when we tried to run proofs of these cases, in spite of efforts such as increasing the amount of space in the SDVS image and modifying the way in which garbage was collected.

In the proof `every_case.proof`, each case is further split into two cases, one in which  $n$  is less

than  $x$  and one in which  $n$  is equal to  $x$ . Although this split entails symbolically executing through the loop twice, this proof was much faster than any that did not involve the case split. The reason for the slowness of the proofs without a case split is essentially the same as the reason (mentioned a few paragraphs ago) for the slowness of the proof with the original invariant: namely, in those proofs without the case split, the prover was not able to recognize the disjointness of various elements of *stdin* and *stdout*.

Both of these cases in *every\_case.proof* have a common part:

```

:

interpret produce_input_information,
interpret go_to_return_from_call_to_ret_cmd_buf_and_status,
interpret fix_array_values_after_call_to_ret_cmd_buf_and_status,
interpret handle_intrinsics_until_end_of_program,
interpret finish_off_non_output_goals,

:

```

The above proof commands accomplish the following:

- Instantiate the formula *input\_condition* for the appropriate range of values to provide information about the current message's input needed to execute symbolically through the loop, e.g. instantiate *input\_condition* with 3 to inform SDVS that the third byte equals the message identifier (*produce\_input\_information*);
- Symbolically execute until the end of the procedure RET\_CMD\_BUF\_AND\_STATUS and then execute **notice** and **consider** commands to “remind” the prover of values that occurred in an array assignment (*go\_to\_return\_from\_call\_to\_ret\_cmd\_buf\_and\_status* and *fix\_array\_values\_after\_call\_to\_ret\_cmd\_buf\_and\_status*);
- Symbolically execute until the beginning of the loop is reached (*handle\_intrinsics\_until\_end\_of\_program*);
- Prove all of those goals generated by the *induct* command that do not have to do with the output condition (*finish\_off\_non\_output\_goals*)

In the case where  $n$  is less than  $x$ , we also interpret the proofs *separate\_input\_places* and *separate\_output\_places* before the common part of the proof given above. These proofs provide SDVS with enough information to deduce that the problematic places that necessitated the case split are disjoint. In the other case (where  $n$  is less than  $x$ ), we interpret the proof *finish\_off\_output\_goal* to prove the goal generated by the *induct* command that involves the output condition.

The central part of *every\_case.proof* is the subproof *handle\_intrinsics\_until\_end\_of\_program*. Stripped of comments and timing commands, this proof is simply the proof command

loop until formula(loopsd) with loop\_body

Thus this subproof interprets the subproof *loop\_body* until *formula(loopsd)* is true, i.e., execution reaches the beginning of the loop. The proof *loop\_body* symbolically executes until (1) the call of an intrinsic function, (2) after the call to `MANAGE_MSG_RETRIEVAL`, (3) at the program label *after\_checksum\_calculation*, or (4) at the beginning of the loop. When (1) occurs, we apply an adalemma for that Ada function. At (2), we again need to “remind” SDVS of lost array values. For (3), we have to prove that the checksum calculation yields the same value as the word formed from the checksum bytes. When (4) is true, the symbolic execution of the loop is finished, the interpretation of *handle\_intrinsics\_until\_end\_of\_program* is finished, and we proceed to proving the goals.

This concludes the discussion of the proof of the correctness assertion. More detail about the proof is contained in Appendix B. It should be noted that in some sense, this proof proceeds by “brute force.” By this we mean that rather than symbolically execute through the loop once and have a proof that takes into account the multiple computation paths through the loop for the different messages, we simply split it up into cases such that there is exactly one computation path (and hence a simpler, in fact a meta-level proof) for each case. Thus the way we have chosen to prove the correctness assertion involves many relatively simple proofs, each of which involves symbolically executing through the loop (and is thus time-consuming), rather than a single, more complicated proof that symbolically executes through the loop once.

One way to improve upon the approach in this section is to use adalemmas for the various procedures in the program. This approach is explored in the next section.

## 6 Adalemmas for the BUILD task.

### 6.1 Why adalemmas?

*Adalemmas* are in essence a special type of state delta that can replace a subprogram call during symbolic execution of the main program. Normally symbolic execution proceeds through the point of a call to a subprogram into the code of the subprogram itself. If, however, an adalemma for the subprogram has been proved, it can be invoked, and, in one step, symbolic execution moves ahead to the return from the call. The adalemma should express all the significant changes to the program state that might result from execution of the subprogram, so that it is irrelevant to the larger proof in progress whether the subprogram code was executed or the adalemma was invoked. Further, the postcondition of the adalemma would normally provide descriptive information about what the subprogram has accomplished that would otherwise have to be proved during symbolic execution of the subprogram code. For example, an adalemma for a sorting procedure might include in its postcondition a quantified statement asserting that the output array is sorted. Finally, if a subprogram is called at several places in a program, invocation of the adalemma replaces several possibly lengthy symbolic executions of the subprogram code. Thus, adalemmas offer significant efficiencies in symbolic execution.

However, efficiency is neither the only nor the most important consideration. The main purposes of adalemmas are as follows:

- (1) To provide a vehicle for expressing and proving abstract properties of a subprogram.
- (2) To permit modular construction of proofs for programs.
- (3) To enable specifications to be stated within the scope of program declarations.

We shall briefly discuss each of these points.

(1) Program specifications are often stated for sections of programs, rather than for an entire main program. This is true for reasons of manageability, conciseness, intelligibility, the fact that program specifications are usually better stated for subprograms, and sundry other considerations. In the case of the portions of the MSX code under consideration in this project, a high-level specification might involve the behavior of interacting asynchronous tasks; it is unclear whether or how formal verification can address the timing considerations involved, so we are led to specifications for individual tasks. The typical situation is that one has a specification either for a subprogram or for some programming unit that can be recast as a subprogram for the purposes of formal verification. Adalemmas in SDVS are expressly designed to meet the needs of this situation.

Further, specifications for programs are usually set up with a considerable degree of abstraction. A program with a completely concrete specification and set of inputs can be verified merely by testing; there is no need for formal methods. But in the usual situation of infinitely many possible inputs, the specifications are necessarily either abstract or incomplete. Adalemmas facilitate the abstract statement of specifications for subprograms.

(2) Just as good mathematical proofs are usually developed through a series of lemmas and subsidiary arguments, and good programming style calls for structured and modularized code, so program verification requires modularization. Without this, proofs of any but the simplest programs become mired in a mass of detail, overwhelming the user and defying comprehension. Adalemmas make it possible to avoid such situations, and to build up proofs for complex programs in a step-wise fashion.

(3) Adalemmas enable specifications to be stated within the scope of program declarations. Without adalemmas, the claim of correctness of a program with respect to its specifications (which as always with SDVS is formulated as a state delta to be proved) must be formulated outside the scope of the program declarations. This is not without its merits, because then the program is treated as a "black box," and the verification covers the declarations in the code as well as the program structure. However, this makes it difficult to state things abstractly, since all parameters involved in the specification, possibly including large collections of constants, have to be asserted in a setting-up phase of the proof preceding the symbolic execution of the program. On the other hand, an adalemma can be formulated in a context in which reference to the program declarations is possible, because all declarations and initializations are automatically generated by the translator; this facilitates abstract treatment and usually increases the generality of the resulting proof.

This point is perhaps easier to see if we examine some of the earlier verification efforts with SDVS, prior to the availability of adalemmas. One of the first examples was a sorting procedure. Since the specification could not be stated for the procedure alone, it had to be stated for an enclosing main program that would actually test the procedure. This program would read in an array, call the procedure, and write out the result. The proof had to contain an induction for the input loop, and a second induction for the output loop, as well as quantified statements expressing the connection between the internal SDVS data structures and the *stdin* and *stdout* arrays. All of this really had nothing to do with verification of the target procedure, and obfuscated the proof. None of this was necessary once the adalemma facility was introduced.

As mentioned above, there are some conceptual advantages to treating the whole program from the outside—the proof isn't dependent upon the declarations—but it is arguable that declarations are neutral from the point of view of verification. There might be a mistake in program declarations that a "from the outside" proof would detect. But there could just as easily be a mistake in the part of that proof containing the assertions that correspond to the internal declarations. In the end, the (human) verifier must compare the printed specifications with the encodings, whether in the proof or the program text. Unlike declarations, the links between the detailed program structure and the specifications of functionality are relatively obscure, so formal verification has something to offer.

## 6.2 A proof strategy for BUILD

### 6.2.1 The BUILD process

In this section we give a reprise of the BUILD task. We assume general familiarity with the code, and our purpose here is merely to give an overview of BUILD to facilitate our description of a verification strategy. Tables 1 and 5 in [1] should illuminate parts of the discussion.

The BUILD task consists mainly of a nonterminating loop. At the beginning of the loop, some (0 or more) *commands* which have been received are placed in APP\_MSGS.CMD\_BUF by a call to SERIAL\_DIG\_CMDS.RET\_CMD\_BUF\_AND\_STATUS. The loop simply repeats if there are no new commands. Eventually, there will be some new commands, so the effect is essentially the same as if we regard each call to SERIAL\_DIG\_CMDS.RET\_CMD\_BUF\_AND\_STATUS as retrieving at least one command. BUILD processes one command at a time, i.e., per iteration, and for practical purposes we can view the incoming commands as an infinite stream. Each command has four bytes, the first byte indicating the type of command, and the remaining three containing the data. The commands supply raw data; the stream of commands must be parsed and the data repackaged into *application messages* meaningful to other modules of the tracking processor. This parsing and repackaging process is the function of the BUILD task. BUILD assembles incoming data in an internal buffer (the App\_Msg array), and when a complete message has been constructed, it copies this into a FIFO queue of messages, the App\_Msg\_Q. Messages are removed from the App\_Msg\_Q by the task MANAGE\_MSG\_RETRIEVAL and passed to the task PROCESS\_MESSAGE.

In this section we focus on the message-building process, independently of the interrupt-driven command reception process or the subsequent message retrieval and processing. That is, we are concerned solely with the BUILD task. The central aspect of this is to show that if the input stream of commands provides a correctly constituted message, then that message is eventually assembled by BUILD and placed in the App\_Msg\_Q. There are numerous other points that would merit verification, e.g. the handling of erroneous input, but in this report we restrict ourselves to verifying the basic functionality (assuming error-free input).

A command has four bytes. The first byte is a code indicating the type of command. Many op codes signify the type of message being initiated, and a few are used to identify the command as a continuation command for a previously initiated message. In the case of Data\_Struct\_Load messages, the op code of the initiating command is 1, while code 8 (Data\_Load\_Cmd) is used for the succeeding commands in this message type. Some types of messages are completed by only one command, i.e, they have at most two actual data bytes besides the op\_code, and others require several commands to convey enough data for a complete message. We are here primarily interested in the latter type, and in particular, the Data\_Struct\_Load messages. These have op\_code 1 and continuation code 8, and come in many sizes. The second byte of a Data\_Struct\_Load message contains information relating to the ultimate disposition of the message, but is not used in the build process. The third byte of a Data\_Struct\_Load message contains a *message\_id*; associated with each message\_id is a specific length for the message.

Let us consider the bytes of a message as being numbered sequentially. The first command for a message contains bytes 1 through 4, and each succeeding command supplies three more message bytes (the high-order byte of these four-byte commands contains the continuation code). The message bytes from the commands are copied and repackaged into an array of words, which is considered the message itself.

The code has two tables of constants:

`TRKING_DATA_STRUC.Words_For_Data_Struct`, providing the actual number of words needed for a message, and

`Cmnds_For_Data_Struct`, providing the number of commands required to convey the message.

The `message_id` is the look-up index for both tables. Note that each command provides three bytes for a message, each word of a message holds two bytes, and the first message byte (the `op_code`) goes in the second byte of the first word. An  $n$ -byte message requires  $(n - 1)/3$  commands and  $(n + 1)/2$  words.

Most of the work of the BUILD task is accomplished by two procedures, `INITIATE_BUILD` and `CONTINUE_BUILD`. `INITIATE_BUILD` is called when a message-initiating command is received. It determines what type of message is to be built. In some cases, the entire message is available from the first command, so `INITIATE_BUILD` sends it directly to the `App_Msg_Q`. Other types of messages (`Data_Struct_Load`, `RAM_Mem_Load`, `EEPROM_Mem_Load`, `Mem_Dump_X_Frames`, and `Chg_Monitor_Loc`) require more than the four bytes available in the first command, so `INITIATE_BUILD` sets the `Build_In_Progress` flag to true, and puts the bytes of the first command into the `App_Msg` intermediate buffer. Each of the message types involves its own unique processing steps at some point, but we have decided to focus on the `Data_Struct_Load` messages (data-structure application messages) because they are critical to the mission and their length generally requires "building," so they provide a good example of the functioning of most parts of the BUILD task.

`CONTINUE_BUILD` is called when `Build_In_Progress` is true, and appends three more bytes to the message being built in the `App_Msg` buffer. In addition, if this is the last command with data for the current message, `CONTINUE_BUILD` copies the `App_Msg` to the `App_Msg_Q`, and then sets BUILD task global variables as required to reset the build process in preparation for the next message.

The following is a summary of the control flow for BUILD:

Start at loop beginning with some commands in `Cmd_Buf`

Call `Initiate_Build` to process the first command:

Assume a `Data_Struct_Load` message.

`Cont_Cmd <---` `Data_Load_Cmd`

Determine `Num_Cmnds_For_App_Msg`, and `Num_Words_For_App_Msg`  
via table look-up.

```

    Copy bytes 1 through 4 of the command into App_Msg(2..4).
    Cmds_Rcvd <--- 1
    Build_In_Progress <--- True
While Cmds_Rcvd < Num_Cmds_For_App_Msg - 1:
    Call CONTINUE_BUILD to add the last three bytes of a
    continuation command to the message being built in the
    App_Msg buffer.
Call CONTINUE_BUILD for the last command for this message, to
    Add the last three bytes to App_Msg,
    copy the completed application message from App_Msg to
    the App_Msg_Q,
    reinitialize task globals.

```

Many details have been omitted from this summary, but this is the general idea of the control flow. Our summary is intended to convey only the actual order of execution, not the precise syntactic structure of the program. In particular, there is no while-loop as shown in the summary; instead, almost the entire task consists of a single loop that extracts a command from the `Cmd_Buf`, then calls either `INITIATE_BUILD` or `CONTINUE_BUILD` depending on the value of the `Build_In_Progress` flag. `CONTINUE_BUILD` may be called even for a command that is not a continuation command; for example, a `No_op_Cmd` may be interspersed at any point during the stream of commands for some application message, and `CONTINUE_BUILD` will write it directly into the `App_Msg_Q`, but not abort the build in progress.

### 6.2.2 Proof strategy

As noted, SDVS does not currently support tasks. Indeed, problems of interaction between asynchronous concurrent tasks are generally intractable, and one should probably not expect any formal program-verification system within the current state of the art to deal with all aspects of such problems. However, it is certainly possible to formulate and prove meaningful statements about tasks. We shall outline a verification approach to the `BUILD` task.

`BUILD` is supposed to copy bytes from the `Cmd_Buf`, which are packaged as three bytes per command, and reassemble them into messages, with the completed message placed in the `App_Msg_Q`. This process is complicated by the facts that the `Cmd_Buf` need not contain at any one time a sufficient number of commands to complete a particular message, and that `No_op` commands may be interspersed with commands continuing some other message. We will deal with the latter complication by assuming that there are no `No_op` commands, and with the former by assuming that as a result of the call by `BUILD` to `SERIAL_DIG_CMDS.RET_CMD_BUF_AND_STATUS`, the `Cmd_Buf` contains enough messages to complete a message. The more general situations are probably not intractable for SDVS, but they are more than is appropriate for this first attempt at verification of `BUILD`.

Consider the beginning of the "for" loop in the `BUILD` task. A state delta expressing the essence of what this part of `BUILD` does should express the following:

Assume that control is at the beginning of the "for" loop, that the first command in the `Cmd_Buf`, namely `Cmd_Buf(1)`, is the first command of a `Data_Struct_Load` message, and that `Cmd_Count` is large enough that the complete message is contained within the commands in the buffer, i.e.,

```
.cmd_count ge .cmds_for_data_struct[.record(cmd_buf[1],third_byte)]
```

Then at a future time, control will again be at this point and the message will have been built and copied into the `App_Msg_Q`.

The state delta would include other information, such as the new values of variables, and the "future time" would be precisely specified.<sup>6</sup>

Some changes in the program syntax are necessary to accomodate SDVS and what we want to do. In the first place, SDVS does not handle tasks, so the `BUILD` task must be converted to a procedure. Secondly, we are interested in proving something about an internal fragment of `BUILD`, the "for" loop, so we must find a way to facilitate this within the requirements of SDVS. Enhancements of SDVS to permit proving lemmas about fragments of code are under consideration, but not yet in place. However, SDVS does have the ability to prove adalemmas about procedures. Any fragment of code which is a sequence of executable statements can be converted to a procedure call by the following artifice: Given a fragment of code

```
--Start of code fragment
.
.
.
.
.
.
--End of code fragment
```

replace it by

```
DECLARE
  PROCEDURE Fragment IS
    BEGIN
      --Start of code fragment
      .
      .
      .
```

---

<sup>6</sup> A more elaborate treatment could drop the assumption that all the necessary commands were in the `Cmd_Buf`, and would consider conditions at the beginning of the outer main loop, instead of the inner "for" loop. In the actual implementation, commands are obtained asynchronously using hardware interrupts. Our test programs replace this by a simple call to "get," so the pending commands can be referred to as in the `stdin` array. Then the action of the routine `SERIAL_DIG_CMDS.RET_CMD_BUF_AND_STATUS` would be described as simply returning one or more commands from the input stream. Although all this seems feasible and not inordinately complicated, we believe the simpler form chosen above to be satisfactory for a first step.

```

        .
        .
        .
        .
        --End of code fragment

    END Fragment;

BEGIN

    Fragment;

END;
```

The result is essentially equivalent to the original code.<sup>7</sup> Whatever one may have wanted to prove about the original code fragment may now be formulated as an adalemma about the procedure `Fragment`. This adalemma can then be used in proofs about larger, enclosing procedures.

In the present case, we propose to prove a suitable adalemma for the “for” loop that is part of the `BUILD` procedure. Such an adalemma could then be used as an aid in proving other adalemmas about larger parts of `BUILD`.<sup>8</sup>

The main elements of the “for” loop are calls to `INITIATE_BUILD` and `CONTINUE_BUILD`. Our first steps are therefore to develop and prove adalemmas for these two procedures.

At the time of this writing, the proofs for the two procedures are complete, but the adalemma and proof for the for-loop are still under development. Also, we have constructed proofs only for a version of the MSX code in which the checksum loop in the `Continue_Build` procedure has been excised; the code is modified so that the test for the correct checksum is always passed. This has been done only because of lack of time to complete the work.

### 6.3 The `INITIATE_BUILD` adalemma

The `INITIATE_BUILD` procedure implements the first step in message processing. It examines the type of incoming messages, which (after elimination of a parity bit by the calling program `BUILD`) is contained in the first byte of the first command for a message. In several cases, all of the message is communicated by the first command, so `INITIATE_BUILD` places the message into the `App_Msg_Q` directly. Various error conditions are also handled by `INITIATE_BUILD`. Here, we concern ourselves only with the `Data_Struct_Load` messages, which do require more than one command and thus at least one call of `CONTINUE_BUILD`. The part of `INITIATE_BUILD` of interest is

```
procedure INITIATE_BUILD (Start_Op_Code : in GLOBAL_TYPES.BYTE;
```

<sup>7</sup>we would like to say “semantically equivalent,” but Ada itself lacks the formal semantics that would be needed to formally establish semantic equivalence.

<sup>8</sup>However, the adalemma could only be used in the context of the modified version of `BUILD`, in which the “for” loop has been transformed to a procedure call. Eventually, enhancements to SDVS allowing adalemmas about arbitrary code fragments will obviate the need for this roundabout procedure.

```

                                Cmd_Buf_Index : in INTEGER) is
Temp_word                      : GLOBAL_TYPES.WORD;
High_Byte_Word                : GLOBAL_TYPES.WORD;
Low_Byte_Word                  : GLOBAL_TYPES.WORD;
Data_Struc_ID_Found           : BOOLEAN;
Start_Build                    : BOOLEAN;
Struc_ID_Index                 : INTEGER;
X                              : INTEGER;
Y                              : INTEGER;
begin
  Start_Build := False;
  case Start_Op_Code is
    when Data_Struc_Load =>
      Data_Struc_ID_Found := False;
      Struc_ID_Index :=
        CONV_BYTE_TO_INTEGER(Cmd_Buf(Cmd_Buf_Index).Third_Byte);
      if (Struc_ID_Index <= TRKING_DATA_STRUC.Num_Data_Struc) and
        (Struc_ID_Index > 0) then
        Cont_Cmd := Data_Load_Cmd;
        Num_Cmds_For_App_Msg := Cmds_For_Data_Struc(Struc_ID_Index);
        Num_Words_For_App_Msg := TRKING_DATA_STRUC.Words_For_Data_Struc(
                                Struc_ID_Index) + 1;

        if (Num_Cmds_For_App_Msg /= 0) then
          Data_Struc_ID_Found := True;
          Start_Build := True;
        end if;
      end if;
      if (Data_Struc_ID_Found = False) then
        .
        .
        .
      end if;
    when RAM_Mem_Load | EEPROM_Mem_Load =>
      .
      .
      .
      .
  end case;
  if Start_Build then
    App_Msg(1) := 0;
    App_Msg(2) := CONV_BYTE_TO_WORD(Start_Op_Code);
    Temp_word := CONV_BYTE_TO_WORD(Cmd_Buf(Cmd_buf_index).Second_Byte);
    High_Byte_Word := SHIFT_LOGICAL_WORD(Temp_word, 8);
    Temp_Word := CONV_BYTE_TO_WORD(Cmd_Buf(Cmd_buf_index).Third_Byte);
    App_Msg(3) := OR_WORD(High_Byte_Word, Temp_Word);
    Temp_word := CONV_BYTE_TO_WORD(Cmd_Buf(Cmd_buf_index).Fourth_Byte);
    App_Msg(4) := SHIFT_LOGICAL_WORD(Temp_word, 8);
    Starting_Cmd_With_Par := Cmd_Buf(Cmd_buf_index).First_Byte;
    Cmds_Rcvd := 1;
    Word_Cntr := 4;
    Build_In_Progress := True;
    Start_Build := False;
  end if;
end INITIATE_BUILD;

```

What this code does is straightforward: After determining that the message is a `Data_Struct_Load`, it sets `Cont_Cmd` to `Data_Load_Cmd`, and determines the numbers of commands and words required for the incoming message, using look-up tables based on the message id—this is kept in `Struc_ID_Index` and is obtained from the third byte of the first command. After some validity checking, control passes to the `if` statement at the end of the procedure. `Start_Build` has been set to `True` by any part of the case statement processing a message that will involve additional commands, and thus must be “built.” Through a sequence of conversions, bit-wise logical shifts, and logical-OR operations, the original four bytes of the command end up repackaged in words 2 through 4 of the `App_Msg` array. Word 1 of `App_Msg` is left zero; it is not involved in the processing of a `Data_Struct_Load` message and will ultimately be ignored by `CONTINUE_BUILD`.

We shall now discuss the corresponding adalemma for the `Data_Struct_Load`-message processing parts of `INITIATE_BUILD`. This adalemma and its proof, as saved by SDVS are:

```
(defadalemma initiate_build.data_struct_load.adalemma
  "msx_program_final_version_sans_checksum.a"      initiate_build
  msx_program_final_version_sans_checksum.app_msgs.initiate_build
  ("start_op_code = .data_struct_load"
   "~.build_in_progress"

  close))")

```

We shall discuss the various parts of the adalemma and its proof. The first group of quoted lines are the precondition, those facts which must be true in order that the adalemma may be applied. In general, these assertions reconstruct the environment within which the target

procedure is called. For example, `INITIATE_BUILD` is called only when `Build_In_Progress` is `False`, so the precondition asserts that fact. When SDVS sets up the environment for proving the adalemma, the preconditions are asserted (as in the proof of any state delta).

The Precondition:

```
"start_op_code = .data_struct_load"
"~.build_in_progress"
"app_msgs.cmd_status_buf[.initiate_build.cmd_buf_index] = .cmd_ok"
"is.byte(start_op_code)"
"is.cmd_bytes_type(app_msgs.cmd_buf[.initiate_build.cmd_buf_index])"
"origin(app_msgs.cmd_buf) le .initiate_build.cmd_buf_index"
".initiate_build.cmd_buf_index le
  (origin(app_msgs.cmd_buf) + range(app_msgs.cmd_buf)) - 1"
"0 lt .record(app_msgs.cmd_buf[.initiate_build.cmd_buf_index],third_byte)"
".record(app_msgs.cmd_buf[.initiate_build.cmd_buf_index],third_byte) le
  .num_data_struct"
".cmds_for_data_struct[
  .record(app_msgs.cmd_buf[.initiate_build.cmd_buf_index],third_byte)] ~= 0")
```

All of the assertions are either facts which are true in the environment in which `INITIATE_BUILD` is called, or which restrict applicability to the case of interest (i.e., the `Data_Struct_Load` messages), and which are actually necessary for the proof. The last three of the preconditions, referring to the third byte of the command for which `INITIATE_BUILD` is called, assert the legitimacy of this value as a message id, and that the corresponding message length is not 0.

The following mod list is a list of places which are altered by `INITIATE_BUILD`.

The Mod List:

```
cont_cmd,
num_cmds_for_app_msg,
num_words_for_app_msg,
app_msgs.cmd_status_buf[.initiate_build.cmd_buf_index],
app_msg[1:4],
starting_cmd_with_par,
cmds_rcvd,
word_cntr,
build_in_progress
```

The proof for the `INITIATE_BUILD` adalemma is short enough that we can discuss it at this point.

The Proof:

```

provebygeneralization g(1)
    using: (q(1),q(2),q(3),q(4),q(5),q(6),q(7)),
close)

```

The provebyaxiom commands at the beginning establish that array places actually changed during symbolic execution are covered by the mod list of the adalemma. Each call to an intrinsic function is handled by an adalemma. The series of notices at the end are connected with a familiar problem: the simplifier automatically has available that  $n \leq m \rightarrow n = m \vee n \leq m - 1$ , but must be guided to extend this further to such facts as  $n \leq m \rightarrow n = m \vee n = m - 1 \vee n = m - 2 \vee n \leq m - 3$ .

## 6.4 The CONTINUE\_BUILD adalemmas

### 6.4.1 Overview

The CONTINUE\_BUILD procedure is called to handle continuation commands, i.e., commands containing parts of a message for which a build is in progress. Since we are considering only Data\_Struct\_Load messages, we will consider only the handling of Data\_Load\_Cmds by CONTINUE\_BUILD; Data\_Load\_Cmd is the value set in Cont\_Cmd by INITIATE\_BUILD when it starts the build of a Data\_Struct\_Load message. The parts of CONTINUE\_BUILD of interest to us are

the following:

```

procedure CONTINUE_BUILD(Cont_Op_Code : in GLOBAL_TYPES.BYTE;
    Cmd_Buf_Index : in INTEGER) is
    App_Msg_Checksum      : GLOBAL_TYPES.WORD;
    App_Msg_Start_Word    : INTEGER;
    Msg_Word_Index       : INTEGER;
    Q_Word_Index         : INTEGER;
    Temp_Word            : GLOBAL_TYPES.WORD;
    High_Byte_Word       : GLOBAL_TYPES.WORD;
    Low_Byte_Word        : GLOBAL_TYPES.WORD;
begin
    if Cont_Op_Code = Cont_Cmd then
        if (Cmds_Rcvd mod 2) = 0 then
            Word_Cntr := Word_Cntr + 1;
            Temp_Word := CONV_BYTE_TO_WORD(Cmd_Buf(Cmd_Buf_Index).Second_Byte);
            High_Byte_Word := SHIFT_LOGICAL_WORD(Temp_Word, 8);
            Low_Byte_Word := CONV_BYTE_TO_WORD(Cmd_Buf(Cmd_Buf_Index).Third_Byte);
            App_Msg(Word_Cntr) := OR_WORD(High_Byte_Word, Low_Byte_Word);
            Word_Cntr := Word_Cntr + 1;
            Temp_Word := CONV_BYTE_TO_WORD(Cmd_Buf(Cmd_Buf_Index).Fourth_Byte);
            App_Msg(Word_Cntr) := SHIFT_LOGICAL_WORD(Temp_Word, 8);
        else
            Low_Byte_Word := CONV_BYTE_TO_WORD(Cmd_Buf(Cmd_Buf_Index).Second_Byte);
            App_Msg(Word_Cntr) := OR_WORD(App_Msg(Word_Cntr), Low_Byte_Word);
            Word_Cntr := Word_Cntr + 1;
            Temp_Word := CONV_BYTE_TO_WORD(Cmd_Buf(Cmd_Buf_Index).Third_Byte);
            High_Byte_Word := SHIFT_LOGICAL_WORD(Temp_Word, 8);
            Low_Byte_Word := CONV_BYTE_TO_WORD(Cmd_Buf(Cmd_Buf_Index).Fourth_Byte);
            App_Msg(Word_Cntr) := OR_WORD(High_Byte_Word, Low_Byte_Word);
        end if;
        Cmds_Rcvd := Cmds_Rcvd + 1;
        if Cmds_Rcvd = Num_Cmds_For_App_Msg then
            App_Msg_Checksum := 0;
            App_Msg_Checksum := App_Msg(Num_Words_For_App_Msg + 1);
            if App_Msg_Checksum = App_Msg(Num_Words_For_App_Msg + 1) then
                if App_Msg_Counter < App_Msg_Q_Size then
                    App_Msg_Start_Word := 2;
                    if (CONV_WORD_TO_BYTE(App_Msg(2)) = RAM_Mem_Load) or
                        (CONV_WORD_TO_BYTE(App_Msg(2)) = EEPROM_Mem_Load) or
                        (CONV_WORD_TO_BYTE(App_Msg(2)) = Mem_Dump_X_Frames) then
                        .
                        .
                        .
                        .
                    end if;
                    Q_Tail := (Q_Tail mod App_Msg_Q_Size) + 1;
                    Num_Words_For_App_Msg := Num_Words_For_App_Msg + 1;
                    Q_Word_Index := 0;
                    for Msg_Word_Index in App_Msg_Start_Word..Num_Words_For_App_Msg loop
                        Q_Word_Index := Q_Word_Index + 1;
                        App_Msg_Q(Q_Tail)(Q_Word_Index) := App_Msg(Msg_Word_Index);
                    end loop;
                    App_Msg_Q(Q_Tail)(CMDS_TYPES.App_Msg_Max) := Q_Word_Index;
                    App_Msg_Counter := App_Msg_Counter + 1;
                end if;
            end if;
        end if;
    end if;
end CONTINUE_BUILD;

```

```

        if App_Msg_Start_Word = 1 then
            null;
        else
            Temp_Word := SHIFT_LOGICAL_WORD(App_Msg(3), -8);
        end if;
        Temp_Word := SHIFT_LOGICAL_WORD(App_Msg(4), -8);
    else
        .
        .
        .
        .
    end if;
else
    .
    .
    .
    .
end if;
Build_In_Progress := False;
end if;
else
    .
    .
    .
    .
end if;
end CONTINUE_BUILD;

```

There are two adalemmas for `CONTINUE_BUILD`; one handles the case where the command to be processed is not the last command for the message being built, and the other is for the case where the current command is the last one. When the last command is processed, `CONTINUE_BUILD` copies the completed message into the `App_Msg_Q`. It is true that the two adalemmas could be combined, because all the functions performed in the “not last” case are also performed in the “last” case; one would add the additional facts to the postcondition in the form of conditional assertions based on whether `#Cmds_Rcvd = .Num_Cmds_For_App_Msg`. However, this complicates the exposition somewhat, and we prefer to use separate adalemmas. We will first discuss the adalemma for the “not last” case.

#### 6.4.2 The “not last” command case

```

  --> high.byte(#app_msg[.word_cntr], .app_msg[.word_cntr] / 256)"
".cmds_rcvd mod 2 = 1
  --> low.byte(#app_msg[.word_cntr],
    .record(app_msgs.cmd_buf[.continue_build.cmd_buf_index],
      second_byte))"
".cmds_rcvd mod 2 = 1
  --> high.byte(#app_msg[.word_cntr + 1],
    .record(app_msgs.cmd_buf[.continue_build.cmd_buf_index],
      third_byte))"
".cmds_rcvd mod 2 = 1
  --> low.byte(#app_msg[.word_cntr + 1],
    .record(app_msgs.cmd_buf[.continue_build.cmd_buf_index],
      fourth_byte)))

```

We shall discuss the various parts of this adalemma.

First consider the following precondition:

```

".build_in_progress"
".app_msgs.cmd_status_buf[.continue_build.cmd_buf_index] = .cmd_ok"
"is.byte(.starting_cmd_with_par)"
"is.byte(.cont_cmd)"
"is.byte(.cont_op_code)"
".cont_cmd = .data_load_cmd"
".cont_op_code = .cont_cmd"
"1 le .cmds_rcvd"
".cmds_rcvd lt .num_cmds_for_app_msg - 1"

".cmds_rcvd mod 2 = .cmds_rcvd - (.cmds_rcvd / 2) * 2"
".cmds_rcvd mod 2 = 0 or .cmds_rcvd mod 2 = 1"

".cmds_rcvd mod 2 = 1 --> low.byte(.app_msg[.word_cntr],0)"

"4 le .word_cntr"
".word_cntr le 78"
"is.cmd_bytes_type(.app_msgs.cmd_buf[.continue_build.cmd_buf_index])"
"origin(app_msgs.cmd_buf) le .continue_build.cmd_buf_index"
".continue_build.cmd_buf_index
  le (origin(app_msgs.cmd_buf) + range(app_msgs.cmd_buf)) - 1"

"forall q (origin(app_msg) le q & q le .word_cntr --> is.word(.app_msg[q]))"

```

The first group of assertions set the environment within which `CONTINUE_BUILD` might be called, and the circumstances under which this adalemma is to be applied. There are two assertions giving properties of the `mod` function—of course, these are mathematically provable facts, but they are not automatically known to the simplifier, so we have put them into the precondition of the adalemma. The user will be responsible for proving these before the adalemma is applied. This is important, because the expression `.cmds_rcvd mod 2` is used in the mod list of this adalemma, and the correct covering properties will not be known to the covering solver unless the possible values of this expression are known. The assertion about `.app_msg[.word_cntr]` is that if an odd number of commands have been received, then the low byte of the last word in the current message is 0. The next group of assertions guarantee that various array indices are in range. The last assertion states that everything in the `.app_msg` array is a “word,” i.e., is an integer in the range 0 ... 65535. SDVS has the built-in type *integer* but the simplifier does not handle subtypes; to deal with this situation, the SDVS Ada translator places guard conditions on its translations of assignment statements for variables declared of a given subtype, to insure that the value assigned is actually in the subtype. If a variable *V* is declared as a word, then the translator output requires that any quantities to be assigned to *V* must be in the range 0 ... 65535. Since members of the `App_Msg` array are later used in assignments to other words, the information that `App_Msg` consists of words must be available. Indeed, there is such a step even within the code for `CONTINUE_BUILD`. Hence, the quantified statement must be part of the precondition to `CONTINUE_BUILD`, not merely proved after its invocation. A similar

statement, with an appropriately enlarged range of subscripts for `.app_msg`, is part of the postcondition.

Next consider the following mod list (in input notation):

```
word_cntr,
app_msg[word_cntr+1-(cmds_rcvd mod 2)],
app_msg[word_cntr+2-(cmds_rcvd mod 2)],
cmds_rcvd
```

These are simply a list of the places which are modified by `CONTINUE_BUILD` when called on a command which is not a "last" command. As it happens, we were able to write expressions for the array subscripts which work out correctly whether or not `.cmds_rcvd` is odd or even—were this not so, we should have been obliged to prove two separate adalemmas, one for each of these cases.

The postcondition is examined in several parts:

```
"forall q (origin(app_msg) le q & q le #word_cntr --> is.word(.app_msg[q]))"
"#word_cntr = (.word_cntr + 2) - .cmds_rcvd mod 2"
"#cmds_rcvd = .cmds_rcvd + 1"
".cmds_rcvd mod 2 = 0 --> #word_cntr = .word_cntr + 2"
```

The quantified statement above asserts, as promised, that `app_msg` is an array of words. Then the new values of `word_cntr` and `cmds_rcvd` are asserted.

```
".cmds_rcvd mod 2 = 0
--> high.byte(#app_msg[word_cntr + 1],
             .record(app_msgs.cmd_buf[.continue_build.cmd_buf_index],
                     second_byte))"
".cmds_rcvd mod 2 = 0
--> low.byte(#app_msg[word_cntr + 1],
            .record(app_msgs.cmd_buf[.continue_build.cmd_buf_index],
                    third_byte))"
".cmds_rcvd mod 2 = 0
--> high.byte(#app_msg[word_cntr + 2],
             .record(app_msgs.cmd_buf[.continue_build.cmd_buf_index],
                     fourth_byte))"
".cmds_rcvd mod 2 = 0 --> low.byte(#app_msg[word_cntr + 2],0)"
```

This group of assertions applies when `.cmds_rcvd` is initially even. In that case, the three bytes of the current command are stored into the two bytes of the next available word in `app_msg` and the high byte of the word after that.

It is appropriate at this point to look at the definitions of the macros `high.byte` and `low.byte`. They are

```
(defmacro high.byte      ;extra facts here because this is used in postconditions
  "0 le x & x le 65535 & y = x / 256 & 0 le y & y le 255 &
```

```

      x = y * 256 + x mod 256"
(x y) nil)

(defmacro low.byte      ;extra facts here because this is used in postconditions
  "0 le x & x le 65535 & y = x mod 256 & 0 le y & y le 255 &
   x = ((x / 256) * 256) + y"
  (x y) nil)

```

The reader will note that these seem redundant; some of what is given is a mathematical consequence of the rest. However, if we left it at that, we should have to prove those consequences at some point; putting them instead in these macros provides the simplifier more information to work with, and eliminates (we hope) the need for the user to reprove these things.

The last group of assertions is for the case that the initial value of `.cmds_rcvd` is an odd integer:

```

".cmds_rcvd mod 2 = 1 --> #word_cntr = .word_cntr + 1"
".cmds_rcvd mod 2 = 1
--> high.byte(#app_msg[.word_cntr],.app_msg[.word_cntr] / 256)"
".cmds_rcvd mod 2 = 1
--> low.byte(#app_msg[.word_cntr],
             .record(app_msgs.cmd_buf[.continue_build.cmd_buf_index],
                     second_byte))"
".cmds_rcvd mod 2 = 1
--> high.byte(#app_msg[.word_cntr + 1],
             .record(app_msgs.cmd_buf[.continue_build.cmd_buf_index],
                     third_byte))"
".cmds_rcvd mod 2 = 1
--> low.byte(#app_msg[.word_cntr + 1],
             .record(app_msgs.cmd_buf[.continue_build.cmd_buf_index],
                     fourth_byte))")

```

This group applies when the number of previously received commands is odd. In such a case, the high byte of the last used word in `App_Msg` is preserved, and the three bytes from the current command are inserted into the low byte of that word, and the two bytes of the next available word in `App_Msg`.

This `CONTINUE_BUILD` adalemma would normally be applied in a situation in which there is a quantified statement expressing the relationship between the `Cmd_Buf` and the current contents of `App_Msg`. The lemma must be constructed so that its application does not cause the deletion of that statement from the `usablequantifiers` list, and so that an appropriately enlarged quantified statement can be proved after the application of the adalemma. These requirements translate into the need for an accurate mod list, and a complete rendering of the new situation in the postcondition.

### 6.4.3 The "last" command case

The second adalemma for `CONTINUE_BUILD` addresses the situation that the current command is in fact the last one required for the build of the message to be complete: this occurs when

```
.cmds_rcvd = .num_cmds_for_app_msg - 1
```

In this case, not only does CONTINUE\_BUILD perform the same steps as before, but it also copies the completed message into the App\_Msg\_Q. Therefore there are correspondingly more places listed in the mod list and more assertions in the postcondition.<sup>9</sup>

The adalemma for the "last" command is

```
(defadalemma continue_build.data_load_cmd.last.not.eeprom.adalemma
  "msx_program_final_version_sans_checksum.a"
  continue_build
  msx_program_final_version_sans_checksum.app_msgs.continue_build
  ("build_in_progress"
    ".app_msgs.cmd_status_buf[.continue_build.cmd_buf_index] = .cmd_ok"
    "is.byte(.starting_cmd_with_par)"
    "is.byte(.cont_cmd)"
    "is.byte(.cont_op_code)"
    ".cont_cmd = .data_load_cmd"
    ".cont_op_code = .cont_cmd"
    "1 le .cmds_rcvd"
    ".cmds_rcvd = .num_cmds_for_app_msg - 1"
    ".cmds_rcvd mod 2 = .cmds_rcvd - (.cmds_rcvd / 2) * 2"
    ".cmds_rcvd mod 2 = 0 or .cmds_rcvd mod 2 = 1"
    ".cmds_rcvd mod 2 = 1 --> low.byte(.app_msg[.word_cntr],0)"
    "4 le .word_cntr"
    ".word_cntr le 78"
    "is.cmd_bytes_type(.app_msgs.cmd_buf[.continue_build.cmd_buf_index])"
    "origin(app_msgs.cmd_buf) le .continue_build.cmd_buf_index"
    ".continue_build.cmd_buf_index
     le (origin(app_msgs.cmd_buf) + range(app_msgs.cmd_buf)) - 1"

    "3 le .num_words_for_app_msg"
    ".num_words_for_app_msg le (range(app_msg) + origin(app_msg)) - 4"

    "forall q (origin(app_msg) le q & q le .word_cntr --> is.word(.app_msg[q]))"

    "(.word_cntr + 2) - .cmds_rcvd mod 2 ge .num_words_for_app_msg + 1"

    ".app_msg_counter lt .app_msg_q_size"

    "0 le .q_tail"
    ".q_tail = 0 --> .app_msg_counter = 0"
    ".q_tail le (range(app_msg_q) + origin(app_msg_q)) - 1"
    ".q_tail lt range(app_msg_q) & .q_tail mod .app_msg_q_size = .q_tail or
     .q_tail = range(app_msg_q) & .q_tail mod .app_msg_q_size = 0"
    "30 mod 30 = 0"
    "is.byte(.app_msg[2])")
```

---

<sup>9</sup> Actually, there is a further case distinction made in CONTINUE\_BUILD: whether the message completed is a RAM\_Mem\_Load, a EEPROM\_Mem\_Load, or a Mem\_Dump\_X\_Frames message; in any of these cases further processing of the message is performed before it is placed in the App\_Msg\_Q. But we are restricting consideration in this report to the Data\_Struct\_Load messages, which do not require any further processing. Nevertheless, we have proved the adalemma for even the more complex situation of the other message types mentioned. This third CONTINUE\_BUILD adalemma will be listed at the end of this section, but will not be discussed further.

```

  = #num_words_for_app_msg - 1"
"#app_msg_counter = .app_msg_counter + 1"
"#build_in_progress = false"))

```

The precondition, mod list, and postcondition of this adalemma are each an extension of the corresponding part of the first adalemma. We shall discuss only the differences.

In the precondition, there are assertions concerning `.num_words_for_app_msg`, which express what is known about this quantity at times when `CONTINUE_BUILD` is invoked. There are several assertions about `.q_tail`, which serve to place it in the correct range, and also to guide the simplifier in determining bounds on the new value, `#q_tail`. This includes arithmetical facts about the result of using the `mod` function, which are mathematically true but not automatically available to the simplifier. The initial value for `.q_tail` is 0, but once anything has been written into the `App_Msg_Q`, `Q_tail` is never again 0. Thus, `.q_tail = 0 --> .app_msg_counter = 0` is true, although this fact is never used anywhere in the proof. (Note that the converse does not hold: `.app_msg_q = 0` is possible even when `.q_tail`  $\neq$  0.) The "`30 mod 30 = 0`" is present merely to coax the simplifier in the right direction; this fact is automatically known if the simplifier is interrogated about it, but apparently the act of interrogation, or including it in the precondition, increases its availability for other behind-the-scenes work of the simplifier. Inserting this arithmetical fact in the precondition saves a few "notice" commands later on in the proof. `App_Msg(2)` contains the message id in its low-order byte. The exact value of `.app_msg[2]` would likely be known to the simplifier at the moment of any particular application of this adalemma, but we are stating and proving the adalemma in a general situation without any knowledge of an exact value. Thus, we have precondition assertions giving needed facts about `.app_msg[2]`.<sup>10</sup>

The mod list is, in user-interface instead of lisp notation,

```

word_cntr,
app_msg[.word_cntr+1-(.cmds_rcvd mod 2)],
app_msg[.word_cntr+2-(.cmds_rcvd mod 2)],
cmds_rcvd,
q_tail,
num_words_for_app_msg,
app_msg_q[.q_tail mod .app_msg_q_size + 1][1:.num_words_for_app_msg + 1],
app_msg_q[.q_tail mod .app_msg_q_size + 1][.app_msg_max],
app_msg_counter,
build_in_progress

```

The additional places are simply those that may be altered when the completed message is copied into the `App_Msg_Q`.

The additional parts of the postcondition are mostly self-explanatory, merely expressing what is accomplished by the additional code executed in the case of a completed message. Noteworthy are the assertions concerning `.app_msg_q`:

<sup>10</sup>In particular, the assertions that the current message is not one of `RAM_Mem_Load`, `EEPROM_Mem_Load`, or `Mem_Dump_X_Frames`.

```

"forall q (1 le q & q le .num_words_for_app_msg
--> #app_msg_q[.q_tail mod .app_msg_q_size + 1][q] = #app_msg[q + 1])"
"#app_msg_q[.q_tail mod .app_msg_q_size + 1][.app_msg_max]
= #num_words_for_app_msg - 1"

```

These indicate that the completed message has been copied to the App\_Msg\_Q.

The two adalemmas we have given suffice for handling the calls to CONTINUE\_BUILD when the message being built is a Data\_Struct\_Load. We also proved an adalemma for the remaining cases of the Data\_Load\_Cmd, namely that it is one of RAM\_Mem\_Load, EEPROM\_Mem\_Load, or Mem\_Dump\_X\_Frames. This we present here, but we shall not discuss it further in this report:

```

"#build_in_progress = false"))
```

It should be noted that the proofs for the adalemmas in the "last" command cases do not close properly. They fail during the final steps of undeclaration of local variables, at a point where all goals apart from the "exited" condition have been proved. We have determined that the problem is due to a bug in SDVS, in which a wrong choice is made for a symbol to be used for a subprogram variable. The bug is possibly some type of "off by one" error. Since all other goals are proved before the bug manifests, we expect that the same proofs we have developed will close properly when the bug is fixed.

## 7 Conclusions

The primary purpose of this verification effort was to stress-test SDVS and help us formulate further research and development strategies. This project lasted only a year, and because (1) this was the first large Ada application verified and (2) SDVS development occurred concurrently with the program verification, we were restricted in the complexity of the specification and amount of code that could be tackled. However, we found this experience very important for identifying weak and missing features in the tools and underlying theory, and it is helping us prioritize future research and development tasks (see [6] for details).

This application has confirmed our belief that it is not always clear how to scale up (i.e., to verify large applications) from experiences with small examples. The Ada program we verified was by far the largest Ada program to be translated by the SDVS Ada translator, and we ran into unexpected storage and time problems. Perhaps some of these problems are unavoidable given the size of the program. But it was only towards the end of the project that we took a more promising approach to the verification of the program: proving adalemmas for some of the more important subprograms. The incorporation of these lemmas into the proof not only modularizes it but shortens it considerably as well. The reason we did not start out with the adalemma approach is that we thought it would be too time-consuming and difficult within one year. But we were mistaken: our original proof strategy without adalemmas – while more straightforward – ultimately proved too time-consuming.

Apart from stress-testing SDVS, the verification project allowed us to enhance the SDVS Ada translator and add to the system three new proof commands that should facilitate long proofs.

Had we more time to work on the project, we would prove more adalemmas about some of the key subprograms (such as `CMD_IN_HANDLER`) and try to prove correctness assertions about more general schedulers and more realistic input conditions.

## 8 Appendix A – The Annotated Program

```
--SDVS comment: We deleted definitions, object declarations, task declarations,
--SDVS comment: and subprogram declarations that we did not need from several of
--SDVS comment: the packages below. But we did not delete completely anything
--SDVS comment: from subprograms we use: if we did not need a particular statement
--SDVS comment: in a subprogram, we commented it out; the statement appears, but
--SDVS comment: only as a comment. The exceptions to the rule are: (1) the
--SDVS comment: subprogram STORE_DATA_STRUC_IN_EEPROM in the package EEPROM_DATA
--SDVS comment: which bears no relation to the real one, (2) the function
--SDVS comment: CHECK_PARITY in the ASM_UTILITY package whose body is written in
--SDVS comment: 1750A assembly, (3) CHG_STATE and RETRIEVE_CUR_STATE in the
--SDVS comment: package MODE_STATE which are used to give us permission to write
--SDVS comment: to EEPROM, and (4) the procedure REPORT_SYSTEM_ERROR in the
--SDVS comment: package TM_DATA which is used to report errors. The packages
--SDVS comment: SERIAL_DIG_CMDS and APP_MSGS are presented in their entirety. For
--SDVS comment: our purposes, the packages GLOBAL_TYPES, CMDS_TYPES, and
--SDVS comment: TRKING_DATA_STRUC contain only type definitions and object
--SDVS comment: declarations used by SERIAL_DIG_CMDS and APP_MSGS.
--SDVS comment:
--SDVS comment: Our deletions by comment are prefixed by '--SDVS delete:;' or by
--SDVS comment: '--SDVS delete ('reason'),' where 'reason' is one of the
--SDVS comment: reasons discussed in Section 4: for example, '--SDVS delete
--SDVS comment: (1750A)' means the deleted line includes a routine whose body is
--SDVS comment: written in 1750A assembly language. If the deleted line is
--SDVS comment: prefixed '--SDVS delete:;' the reason is given either within a
--SDVS comment: few lines preceding the deletion, or at the beginning of the
--SDVS comment: subprogram in which the statement appears.

-- 02/28/92  R. Pham      Instantiate Shift functions using UNSIGNED_WORD as
--                          result type
-- 03/02/92  R. Pham      Instantiate functions using UNSIGNED_BYTE
-- 03/05/92  S. Hutton    Modified for tracking processor
-----

--SDVS comment: This package instantiates generic functions from the Tartan
--SDVS comment: supplied INTRISICS package. The functions perform bit
--SDVS comment: manipulations. We needed only a few of the instantiated
--SDVS comment: functions. To compile and execute the code with the
--SDVS comment: Verdirx compiler at Aerospace, we supplied Ada code for
--SDVS comment: the functions we needed. In the final SDVS proofs, this
--SDVS comment: code was not used: we used adalemmas to characterize
--SDVS comment: their behavior. These adalemmas were not proved.

--SDVS delete (with): with GLOBAL_TYPES;
--SDVS delete (with): with INTRINSICS;   use INTRINSICS;

package INTRINSIC_FUNCTIONS is

  --SDVS comment: Cmd_Unpacked gets a value by the call to MEMORY_MANAGER.READ_FIFO,
  --SDVS comment: which is written in 1750A. We replaced this call by the "for" loop which
  --SDVS comment: gets 4 bytes from the input.
  --SDVS delete (1750A):  MEMORY_MANAGER.READ_FIFO(Cmd_In_FIFO_Addr,
  --SDVS delete (1750A):                                Cmd_Unpacked'address,
  --SDVS delete (1750A):                                Cmd_Size);
  for i in 1 .. 4 loop --SDVS replace
    get(Cmd_Unpacked(i)); --SDVS replace
  end loop; --SDVS replace

  -- Initialize command status.
  Cmd_Status := Cmd_OK;

  --SDVS comment: The next two assignment statements and the "if" statement are
  --SDVS comment: used to determine the IO_Status_Word and the FIFO_Not_Empty_Count
  --SDVS comment: for the command just obtained. These values are eventually passed

```

```

--SDVS comment: to APP_MSGS.RET_LATEST_CMDS which processes the information for
--SDVS comment: housekeeping telemetry. RET_LATEST_CMDS is never called in the
--SDVS comment: target software. For this reason and because the code below uses
--SDVS comment: intrinsic functions (supplied for the Tartan compiler only),
--SDVS comment: we have deleted the assignment statements and
--SDVS comment: the "if" statement. However, because the IO_Status_Word is assigned
--SDVS comment: to an out parameter of type "word" in a procedure call, SDVS requires
--SDVS comment: that, in the symbolic execution of this call, the out parameter
--SDVS comment: value be in the range 0..255. Thus, we arbitrarily assign
--SDVS comment: 0 to IO_Status_Word to meet this constraint.
    -- Read Spacecraft IO #1 Status after the data is read out of the
    -- FIFO but before the FIFO is reset or receives the next message.
    -- Refer to TP/DHS IDS, page 6.

---

```
--      TASK BUILD
```

---

```
-- PURPOSE : This task first checks if there is any commands
--            to be processed by calling SERIAL_DIG_CMDS. If no command
--            is available to be processed, then the task 'sleeps' for
--            two seconds and repeats the task.
--
--            If there are commands to be processed, then the cmd buffer,
--            status buffer and the other associated variables are retrieved
--            from SERIAL_DIG_CMDS. For each command in the buffer, its status
--            is checked for errors such as parity error and FIFO not
--            empty and command lost errors. Then, either CONTINUE_BUILD
--            or INITIATE_BUILD is called to build the application message(s).
--            out of commands.
--
--            First the type of application to be built is determined.
--            If the application message has a checksum, then the message is
--            built in the form to validate the checksum. Once the checksum
--            is verified, the application message is stored in the queue of
--            application messages.
--
--            A queue of the last 75 commands is also maintained to be
--            collected by TM.COLLECT.
--
--            This task does not have any entry points.

--      TASK PROCESS_MSG
-----
-- PURPOSE: This task retrieves and processes the next
--           available application message from the application
--           message queue.

--           This task continuously initiates a rendezvous with
--           MANAGE_MSG_RETRIEVAL at the entry point RET_NEXT_MSG.
--           This task does not have any entry points.
--
-- NOTES:
--
-- CHANGE HISTORY:
--   10/16/91   B. Na       Initial Version
--   mm/dd/yy   B. Na       Build 2 Changes
--
-----

--SDVS--SDVS--SDVS--SDVS--SDVS--SDVS--SDVS--SDVS--SDVS--SDVS--SDVS--SDVS--SDVS
--SDVS The task PROCESS_MSG processes 11 types of application messages.--SDVS
--SDVS Since we are only interested in data-structure messages and the --SDVS
--SDVS messages are processed in an Ada "case" statement, we --SDVS
--SDVS deleted all the statements in all of the cases (and substituted --SDVS
--SDVS the "null" statement for them) except for the --SDVS
--SDVS Data_Struct_Load case. Any other uncommented deletions are for --SDVS
--SDVS assignments to objects that are used only in the deleted cases. --SDVS
--SDVS--SDVS--SDVS--SDVS--SDVS--SDVS--SDVS--SDVS--SDVS--SDVS--SDVS--SDVS--SDVS

-----
--      INITIATE_BUILD
-----

```

```

-----
-- PURPOSE : This procedure initiates the application message
--            building when called by APP_MSGS.BUILD. The rules for
--            building an app_msg to verify the checksum are as follows:
--
--            1) app_msg(1) is blank. This is so that after the
--               checksum is verified, the header for RAM_mem_Load,
--               EEPROM_mem_load, and Mem_Dump_X_Frames can be
--               easily modified to store the address in 32 bits.
--
--            2) app_msg(2) contains the initial data op-code for
--               the application msg.
--
--            3) if more than one command is required for an application
--               message then the data associated with the checksum is
--               stored in app_msg(3)..app_msg(n). App_msg(n) is a
--               complete word. There is not a spare byte at the end.
--               App_msg(n+1) contains the checksum.

## 9 Appendix B – The Proofs

### 9.1 Definitions, etc. used in the main proof

```
; -*- Syntax: Common-lisp; Package: USER; Mode: LISP -*-% ; File name
: /u/versys/msx/infinite_sequence_data_structure_messages.defs

;;; This file contains the formulas, macros and proofs used in the main proof
;;; (found in file
;;; /u/versys/msx/infinite_sequence_data_structure_messages.proof).
;;; This file is for the most part organized bottom-up: that is, definitions,
;;; lemmas, etc. are introduced immediately before they are used. The major
;;; exception to this is the first section which contains macros. A top-down
;;; explanation of main proof is given in the body of the technical report.
```

#### 9.1.1 Macros

```
;;; Macro section

;; Macro is.byte is a predicate which is true if x is between 0 and 255
;; inclusive, false otherwise.

(defmacro is.byte
  "0 le x & x le 255"
  (x) nil)

;; Macro is.word is a predicate which is true if x is between 0 and 65536
;; inclusive, false otherwise.

(defmacro is.word
  "0 le x & x le 65535"
  (x) nil)

;; Macro mk.word is a function which returns the value of a word whose
;; high-order bits are the byte a and whose low-order bits are the byte b.

(defmacro mk.word
  "256 * a + b"
  (a b) nil)

;; Macro all.high is a predicate which returns true if x is a word all of
;; whose low-order bits are 0, false otherwise.

(defmacro all.high
  "0 le x & x le 65535 & x mod 256 = 0" ; The is.word macro is not used
```

```

(x) nil)                                ; here as SDVS does not currently
                                         ; handle nested macros

;; Macro all.low is a predicate which returns true if x is a word all of whose
;; low-order bits are 0, false otherwise.

(defmacro all.low
  "0 le x & x le 255"
  (x) nil)

;; Macro high.bits is a function whose value is the high-order bits of a word.

(defmacro high.bits
  "x / 256"
  (x) nil)

;; Macro low.bits is a function whose value is the low-order bits of a word.
(defmacro low.bits
  "x mod 256"
  (x) nil)

```

### 9.1.2 Timing proofs

```

;;; Proofs used for timing. These proofs are used to give the date at various points
;;; in the main proof if the variable timing is set to true.

;; Proof printdate prints the date if the timing flag is true, does nothing otherwise.

(defproof printdate_if_wanted
  "(if timing
    then printdate)")

;; Proof printdate simply prints the date

(defproof printdate
  "(date)")

```

### 9.1.3 Formulas used in the precondition

```

;;; The following section contains formulas used in the precondition
;;; of the main state delta (infinite_sequence_data_structure_messages.sd).

;;; The following formulas (which are accompanied below by their
;;; proofs) are included in the precondition to avoid re-proving for
;;; each run with a different step_case.proof

```

```

;;; The state deltas input_places_disjoint.sd and
;;; output_places_disjoint.sd are used in the step case to prove
;;; that the input and output places associated with the nth message are
;;; disjoint from the places mentioned in the output condition (i.e., those
;;; associated with the xth message).

;; State delta input_places_disjoint.sd is applied in the  $n < x$  case in the
;; step case of the induction so that the prover is able to deduce that the input
;; places for the nth message are disjoint from the input places for the xth message.

(defsd input_places_disjoint.sd
  "[sd pre: ( formula(msg_input_begins_at_definition),  $n \geq 1$ ,  $n < x$ ,
              formula(msg_in_lh_definition), formula(allowed_message_ids))

### 9.1.6 Proofs used in the main proof

```
;;; Proofs used in the main proof. Each of these proofs is embedded
;;; in setflag and comment commands that allow the traceflag to be turned off
;;; in the main proof so that an abbreviated trace can be obtained. Each
;;; proof is also surrounded by printdate_if_wanted commands that allow timing
;;; information to be obtained if the timing variable is set to true in the
;;; main proof.
```

```

;;; The following three proofs are used before the loop induction in the main
;;; proof.

;; Proof fix_constant_arrays fixes problems with the initialization of
;; the large constant arrays WORDS_FOR_DATA_STRUC_TYPE and CMDS_FOR_DATA_STRUC_TYPE.

(defproof fix_constant_arrays
  "(setflag traceflag on,
    comment \ "Beginning interpretation of fix_constant_arrays... \ ",
